

DEVELOPMENT THROUGH THE  
**LIFESPAN**

*Seventh Edition*

LAURA E. BERK

# Brief Contents

---

## **PART I:** THEORY AND RESEARCH IN HUMAN DEVELOPMENT

- 1** History, Theory, and Research Strategies 2

## **PART II:** FOUNDATIONS OF DEVELOPMENT

- 2** Genetic and Environmental Foundations 42
- 3** Prenatal Development, Birth, and the Newborn Baby 74

## **PART III:** INFANCY AND TODDLERHOOD: THE FIRST TWO YEARS

- 4** Physical Development in Infancy and Toddlerhood 114
- 5** Cognitive Development in Infancy and Toddlerhood 148
- 6** Emotional and Social Development in Infancy and Toddlerhood 182

## **PART IV:** EARLY CHILDHOOD: TWO TO SIX YEARS

- 7** Physical and Cognitive Development in Early Childhood 214
- 8** Emotional and Social Development in Early Childhood 256

## **PART V:** MIDDLE CHILDHOOD: SIX TO ELEVEN YEARS

- 9** Physical and Cognitive Development in Middle Childhood 292
- 10** Emotional and Social Development in Middle Childhood 334

## **PART VI:** ADOLESCENCE: THE TRANSITION TO ADULTHOOD

- 11** Physical and Cognitive Development in Adolescence 366
- 12** Emotional and Social Development in Adolescence 406

## **PART VII:** EARLY ADULTHOOD

- 13** Physical and Cognitive Development in Early Adulthood 436
- 14** Emotional and Social Development in Early Adulthood 468

## **PART VIII:** MIDDLE ADULTHOOD

- 15** Physical and Cognitive Development in Middle Adulthood 506
- 16** Emotional and Social Development in Middle Adulthood 536

## **PART IX:** LATE ADULTHOOD

- 17** Physical and Cognitive Development in Late Adulthood 568
- 18** Emotional and Social Development in Late Adulthood 608

## **PART X:** THE END OF LIFE

- 19** Death, Dying, and Bereavement 644

# About the Author

**Laura E. Berk** is a distinguished professor of psychology at Illinois State University, where she has taught child, adolescent, and lifespan development for more than three decades. She received her bachelor's degree in psychology from the University of California, Berkeley, and her master's and doctoral degrees in child development and educational psychology from the University of Chicago.

She has been a visiting scholar at Cornell University, UCLA, Stanford University, and the University of South Australia.

Berk has published widely on the effects of school environments on children's development, the development of private speech, and the role of make-believe play in development. Her empirical studies have attracted the attention of the general public, leading to contributions to *Psychology Today* and *Scientific American*. She has also been featured on National Public Radio's *Morning Edition* and in *Parents Magazine*, *Wondertime*, and *Reader's Digest*.

Berk has served as a research editor of *Young Children*, a consulting editor for *Early Childhood Research Quarterly*, and as an associate editor of the *Journal of Cognitive Education and Psychology*. She is a frequent contributor to edited volumes, having written the article on social development for *The Child: An Encyclopedic Companion* and the article on Vygotsky for *The Encyclopedia of Cognitive Science*. She is coauthor of the chapter on make-believe play and self-regulation in the *Sage Handbook of Play in Early Childhood* and the chapter on psychologists writing textbooks in *Career Paths in Psychology: Where Your Degree Can Take You*, published by the American Psychological Association.

Berk's books include *Private Speech: From Social Interaction to Self-Regulation*; *Scaffolding Children's Learning: Vygotsky and Early Childhood Education*; *Landscapes of Development: An Anthology of Readings*; and *A Mandate for Playful Learning in Preschool: Presenting the Evidence*. In addition to *Development Through the Lifespan*, she is author of the best-selling texts *Child Development* and *Infants, Children, and Adolescents*, published by Pearson. Her book for parents and teachers is *Awakening Children's Minds: How Parents and Teachers Can Make a Difference*.

Berk is active in work for children's causes. She serves on the governing boards of the Illinois Network of Child Care Resource and Referral Agencies and of Artolution, an organization devoted to engaging children, youths, and families in collaborative public art projects around the world as a means of promoting resilience and relief from trauma. Berk has been designated a YWCA Woman of Distinction for service in education. She is a fellow of the American Psychological Association, Division 7: Developmental Psychology.

# Features at a Glance

## SOCIAL ISSUES: HEALTH

- Family Chaos Undermines Parents' and Children's Well-Being 26
- The Pros and Cons of Reproductive Technologies 52
- The Nurse–Family Partnership: Reducing Maternal Stress and Enhancing Child Development Through Social Support 90
- A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies 102
- Does Child Care in Infancy Threaten Attachment Security and Later Adjustment? 202
- Family Stressors and Childhood Obesity 296
- Children's Eyewitness Testimony 361
- Lesbian, Gay, and Bisexual Youths: Coming Out to Oneself and Others 382
- Childhood Attachment Patterns and Adult Romantic Relationships 480
- Partner Abuse 488
- The Silver Lining in Life's Adversities 523
- Generative Adults Tell Their Life Stories 540
- Grandparents Rearing Grandchildren: The Skipped-Generation Family 554
- Interventions for Caregivers of Older Adults with Dementia 592
- Elder Suicide 618

## SOCIAL ISSUES: EDUCATION

- Baby Learning from TV and Video: The Video Deficit Effect 157
- Magnet Schools: Equal Access to High-Quality Education 327
- Media Multitasking Disrupts Learning 400
- Development of Civic Engagement 419
- How Important Is Academic Engagement in College for Successful Transition to the Labor Market? 461
- The Art of Acting Enhances Cognitive Functioning in Older Adults 603

## BIOLOGY AND ENVIRONMENT

- Resilience 10
- The Tutsi Genocide and Epigenetic Transmission of Maternal Stress to Children 71
- The Mysterious Tragedy of Sudden Infant Death Syndrome 106
- Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults 122
- “Tuning In” to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning 139
- Infantile Amnesia 164
- Parental Depression and Child Development 187
- Development of Shyness and Sociability 192
- Autism and Theory of Mind 243
- Transgender Children 281
- Children with Attention-Deficit Hyperactivity Disorder 309
- Bullies and Their Victims 349
- Sex Differences in Spatial Abilities 396
- Two Routes to Adolescent Delinquency 431
- Telomere Length: A Marker of the Impact of Life Circumstances on Biological Aging 439
- Anti-Aging Effects of Dietary Calorie Restriction 511
- What Factors Promote Psychological Well-Being in Midlife? 546
- What Can We Learn About Aging from Centenarians? 572
- Experience Corps: Promoting Retired Adults' Physical and Mental Health and Children's Academic Success 638
- Music as Palliative Care for Dying Patients 653

## CULTURAL INFLUENCES

- The Baby Boomers Reshape the Life Course 12
- Immigrant Youths: Adapting to a New Land 32
- The African-American Extended Family 63
- Cultural Variation in Infant Sleeping Arrangements 126
- Social Origins of Make-Believe Play 168
- The Role of Fathers' Involvement in Children's Development 205
- Why Are Children from Asian Cultures Advanced in Drawing Skills? 226
- Children in Village and Tribal Cultures Observe and Participate in Adult Work 237
- Cultural Variations in Personal Storytelling: Implications for Early Self-Concept 259
- Ethnic Differences in the Consequences of Physical Punishment 270
- The Flynn Effect: Massive Generational Gains in IQ 319
- Impact of Ethnic and Political Violence on Children 359
- Identity Development Among Ethnic Minority Adolescents 412
- Masculinity at Work: Men Who Choose Nontraditional Careers 464
- Is Emerging Adulthood Really a Distinct Stage of Development? 474
- Menopause as a Biocultural Event 514
- The New Old Age 613
- Cultural Variations in Mourning Behavior 664

## APPLYING WHAT WE KNOW

- Steps Prospective Parents Can Take Before Conception to Increase the Chances of a Healthy Baby 55
- Do's and Don'ts for a Healthy Pregnancy 92
- Soothing a Crying Baby 107
- Reasons to Breastfeed 128
- Features of a High-Quality Home Life: The HOME Infant–Toddler Subscales 170
- Signs of Developmentally Appropriate Infant and Toddler Child Care 172
- Supporting Early Language Learning 178
- Encouraging Affectionate Ties Between Infants and Their Preschool Siblings 206
- Helping Toddlers Develop Compliance and Self-Control 209
- Signs of Developmentally Appropriate Early Childhood Programs 248
- Helping Children Manage Common Fears of Early Childhood 262
- Positive Parenting 271
- Regulating Screen Media Use 275
- Providing Developmentally Appropriate Organized Sports in Middle Childhood 302
- Signs of High-Quality Education in Elementary School 325
- Fostering a Mastery-Oriented Approach to Learning 341
- Helping Children Adjust to Their Parents' Divorce 355
- Handling Consequences of Teenagers' New Cognitive Capacities 393
- Supporting High Achievement in Adolescence 399
- Supporting Healthy Identity Development 413
- Preventing Sexual Coercion 455
- Resources That Foster Resilience in Emerging Adulthood 475
- Keeping Love Alive in a Romantic Partnership 482
- Strategies That Help Dual-Earner Couples Combine Work and Family Roles 501
- Reducing Cancer Incidence and Deaths 517
- Reducing the Risk of Heart Attack 518
- Managing Stress 521
- Facilitating Adult Reentry to College 533
- Ways Middle-Aged Parents Can Promote Positive Ties with Their Adult Children 552
- Relieving the Stress of Caring for an Aging Parent 558
- Ingredients of Effective Retirement Planning 563
- Increasing the Effectiveness of Educational Experiences for Older Adults 604
- Fostering Adaptation to Widowhood in Late Adulthood 629
- Discussing Concerns About Death with Children and Adolescents 644
- Communicating with Dying People 650
- Suggestions for Resolving Grief After a Loved One Dies 663

A Personal Note to Students *xiv*

Preface for Instructors *xv*

## PART I

### THEORY AND RESEARCH IN HUMAN DEVELOPMENT

#### chapter 1

##### History, Theory, and Research Strategies 2

A Scientific, Applied, and Interdisciplinary Field 5

Basic Issues 5

Continuous or Discontinuous Development? 6

One Course of Development or Many? 6

Relative Influence of Nature and Nurture? 7

The Lifespan Perspective: A Balanced Point of View 7

Development Is Lifelong 8

Development Is Multidimensional and Multidirectional 8

Development Is Plastic 9

Development Is Influenced by Multiple, Interacting Forces 9

■ **BIOLOGY AND ENVIRONMENT** *Resilience* 10

■ **CULTURAL INFLUENCES** *The Baby Boomers Reshape the Life Course* 12

Scientific Beginnings 12

Darwin: Forefather of Scientific Child Study 12

The Normative Period 14

The Mental Testing Movement 14

Mid-Twentieth-Century Theories 14

The Psychoanalytic Perspective 14

Behaviorism and Social Learning Theory 16

Piaget's Cognitive-Developmental Theory 17

Recent Theoretical Perspectives 19

Information Processing 19

Developmental Neuroscience 20

Ethology and Evolutionary Developmental Psychology 21

Vygotsky's Sociocultural Theory 22

Ecological Systems Theory 23

■ **SOCIAL ISSUES: HEALTH** *Family Chaos Undermines Parents' and Children's Well-Being* 25

Comparing and Evaluating Theories 26

Studying Development 26

Common Research Methods 28

General Research Designs 31

■ **CULTURAL INFLUENCES** *Immigrant Youths: Adapting to a New Land* 32

Designs for Studying Development 35

Ethics in Lifespan Research 37

Summary 39

Important Terms and Concepts 41

## PART II

### FOUNDATIONS OF DEVELOPMENT

#### chapter 2

##### Genetic and Environmental Foundations 42

Genetic Foundations 44

The Genetic Code 44

The Sex Cells 44

Boy or Girl? 45

Multiple Offspring 45

Patterns of Gene–Gene Interactions 46

Chromosomal Abnormalities 50

Reproductive Choices 51

Genetic Counseling 51

■ **SOCIAL ISSUES: HEALTH** *The Pros and Cons of Reproductive Technologies* 52

Prenatal Diagnosis and Fetal Medicine 53

Adoption 55

Environmental Contexts for Development 56

The Family 57

Socioeconomic Status and Family Functioning 58

Poverty 58

Affluence 60

Beyond the Family: Neighborhoods and Schools 60

The Cultural Context 62

■ **CULTURAL INFLUENCES** *The African-American Extended Family* 63

Understanding the Relationship Between Heredity and Environment 66

The Question, “How Much?” 67

The Question, “How?” 68

■ **BIOLOGY AND ENVIRONMENT** *The Tutsi Genocide and Epigenetic Transmission of Maternal Stress to Children* 71

Summary 72

Important Terms and Concepts 73

#### chapter 3

##### Prenatal Development, Birth, and the Newborn Baby 74

Prenatal Development 76

Conception 76

Germinal Period 76

Period of the Embryo 78

Period of the Fetus 79

Prenatal Environmental Influences 81

Teratogens 81

Other Maternal Factors 88

■ **SOCIAL ISSUES: HEALTH** *The Nurse–Family Partnership: Reducing Maternal Stress and Enhancing Child Development Through Social Support* 90

The Importance of Prenatal Health Care 91

**Childbirth** 92

The Stages of Childbirth 93

The Baby's Adaptation to Labor and Delivery 94

The Newborn Baby's Appearance 94

Assessing the Newborn's Physical Condition: The Apgar Scale 94

**Approaches to Childbirth** 95

Natural, or Prepared, Childbirth 95

Home Delivery 96

**Medical Interventions** 96

Fetal Monitoring 96

Labor and Delivery Medication 97

Cesarean Delivery 97

**Preterm and Low-Birth-Weight Infants** 97

Preterm versus Small-for-Date Infants 98

Consequences for Caregiving 98

Interventions for Preterm Infants 99

**The Newborn Baby's Capacities** 101

Reflexes 101

■ **SOCIAL ISSUES: HEALTH** *A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies* 102

States of Arousal 104

■ **BIOLOGY AND ENVIRONMENT** *The Mysterious Tragedy of Sudden Infant Death Syndrome* 106

Sensory Capacities 108

Neonatal Behavioral Assessment 110

**Adjusting to the New Family Unit** 111

**Summary** 111

**Important Terms and Concepts** 113

## PART III

### INFANCY AND TODDLERHOOD: THE FIRST TWO YEARS

## chapter 4

### Physical Development in Infancy and Toddlerhood 114

**Body Growth** 116

Changes in Body Size and Muscle–Fat Makeup 116

Changes in Body Proportions 117

Individual and Group Differences 117

**Brain Development** 117

Development of Neurons 117

Measures of Brain Functioning 119

Development of the Cerebral Cortex 120

Sensitive Periods in Brain Development 121

■ **BIOLOGY AND ENVIRONMENT** *Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults* 122

Changing States of Arousal 125

■ **CULTURAL INFLUENCES** *Cultural Variation in Infant Sleeping Arrangements* 126

**Influences on Early Physical Growth** 127

Heredity 127

Nutrition 127

Malnutrition 129

**Learning Capacities** 130

Classical Conditioning 130

Operant Conditioning 131

Habituation 131

Imitation 132

**Motor Development** 133

The Sequence of Motor Development 134

Motor Skills as Dynamic Systems 135

Fine-Motor Development: Reaching and Grasping 136

**Perceptual Development** 137

Hearing 138

■ **BIOLOGY AND ENVIRONMENT** *“Tuning In” to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning* 139

Vision 140

Intermodal Perception 143

Understanding Perceptual Development 144

**Summary** 146

**Important Terms and Concepts** 147

## chapter 5

### Cognitive Development in Infancy and Toddlerhood 148

**Piaget's Cognitive-Developmental Theory** 150

Piaget's Ideas About Cognitive Change 150

The Sensorimotor Stage 151

Follow-Up Research on Infant Cognitive Development 153

Evaluation of the Sensorimotor Stage 156

■ **SOCIAL ISSUES: EDUCATION** *Baby Learning from TV and Video: The Video Deficit Effect* 157

**Information Processing** 160

A General Model of Information Processing 160

Attention 161

Memory 162

Categorization 163

■ **BIOLOGY AND ENVIRONMENT** *Infantile Amnesia* 164

Evaluation of Information-Processing Findings 166

**The Social Context of Early Cognitive Development** 166

**Individual Differences in Early Mental Development** 167

Infant and Toddler Intelligence Tests 167

■ **CULTURAL INFLUENCES** *Social Origins of Make-Believe Play* 168

Early Environment and Mental Development 169

Early Intervention for At-Risk Infants and Toddlers 172

- Language Development** 173  
 Theories of Language Development 174  
 Getting Ready to Talk 175  
 First Words 176  
 The Two-Word Utterance Phase 177  
 Individual and Cultural Differences 177  
 Supporting Early Language Development 178

**Summary** 180

**Important Terms and Concepts** 181

## chapter 6

### Emotional and Social Development in Infancy and Toddlerhood 182

**Erikson's Theory of Infant and Toddler Personality** 184

- Basic Trust versus Mistrust 184
- Autonomy versus Shame and Doubt 184

**Emotional Development** 184

- Basic Emotions 185

■ **BIOLOGY AND ENVIRONMENT** *Parental Depression and Child Development* 187

- Understanding and Responding to the Emotions of Others 188
- Emergence of Self-Conscious Emotions 188
- Beginnings of Emotional Self-Regulation 189

**Temperament and Development** 190

- The Structure of Temperament 190
- Measuring Temperament 191
- Stability of Temperament 191

■ **BIOLOGY AND ENVIRONMENT** *Development of Shyness and Sociability* 192

- Genetic and Environmental Influences 193
- Temperament and Child Rearing: The Goodness-of-Fit Model 195

**Development of Attachment** 196

- Bowlby's Ethological Theory 196
- Measuring the Security of Attachment 197
- Stability of Attachment 198
- Cultural Variations 199
- Factors That Affect Attachment Security 199

■ **SOCIAL ISSUES: HEALTH** *Does Child Care in Infancy Threaten Attachment Security and Later Adjustment?* 202

- Multiple Attachments 203

■ **CULTURAL INFLUENCES** *The Role of Fathers' Involvement in Children's Development* 205

- Attachment and Later Development 205

**Self-Development** 206

- Self-Awareness 206
- Categorizing the Self 208
- Self-Control 208

**Summary** 210

**Important Terms and Concepts** 211

**MILESTONES** *Development in Infancy and Toddlerhood* 212

## PART IV

### EARLY CHILDHOOD: TWO TO SIX YEARS

## chapter 7

### Physical and Cognitive Development in Early Childhood 214

**PHYSICAL DEVELOPMENT** 216

**A Changing Body and Brain** 216

- Skeletal Growth 217
- Brain Development 217

**Influences on Physical Growth and Health** 219

- Heredity and Hormones 219
- Nutrition 219
- Infectious Disease 220
- Childhood Injuries 221

**Motor Development** 222

- Gross-Motor Development 223
- Fine-Motor Development 224
- Individual Differences in Motor Skills 225

■ **CULTURAL INFLUENCES** *Why Are Children from Asian Cultures Advanced in Drawing Skills?* 226

**COGNITIVE DEVELOPMENT** 227

**Piaget's Theory: The Preoperational Stage** 227

- Advances in Mental Representation 227
- Make-Believe Play 227
- Symbol-Real-World Relations 228
- Limitations of Preoperational Thought 229
- Follow-Up Research on Preoperational Thought 231
- Evaluation of the Preoperational Stage 232
- Piaget and Education 233

**Vygotsky's Sociocultural Theory** 234

- Private Speech 234
- Social Origins of Early Childhood Cognition 235
- Vygotsky and Early Childhood Education 235
- Evaluation of Vygotsky's Theory 236

**Information Processing** 236

- Executive Function 236

■ **CULTURAL INFLUENCES** *Children in Village and Tribal Cultures Observe and Participate in Adult Work* 237

- Memory 239
- The Young Child's Theory of Mind 241
- Early Childhood Literacy 242

■ **BIOLOGY AND ENVIRONMENT** *Autism and Theory of Mind* 243

- Early Childhood Mathematical Reasoning 244

**Individual Differences in Mental Development** 245

- Home Environment and Mental Development 245
- Preschool, Kindergarten, and Child Care 246
- Educational Media 248

<b>Language Development</b>	249
Vocabulary	250
Grammar	251
Conversation	252
Supporting Language Development in Early Childhood	252

**Summary** 253

**Important Terms and Concepts** 255

## chapter 8

### Emotional and Social Development in Early Childhood 256

**Erikson's Theory: Initiative versus Guilt** 258

**Self-Understanding** 258

    Foundations of Self-Concept 258

■ **CULTURAL INFLUENCES** *Cultural Variations in Personal Storytelling: Implications for Early Self-Concept* 259

    Emergence of Self-Esteem 260

**Emotional Development** 260

    Understanding Emotion 260

    Emotional Self-Regulation 261

    Self-Conscious Emotions 262

    Empathy and Sympathy 262

**Peer Relations** 263

    Advances in Peer Sociability 263

    First Friendships 265

    Peer Relations and School Readiness 266

    Parental Influences on Early Peer Relations 266

**Foundations of Morality and Aggression** 267

    The Psychoanalytic Perspective 267

    Social Learning Theory 268

■ **CULTURAL INFLUENCES** *Ethnic Differences in the Consequences of Physical Punishment* 270

    The Cognitive-Developmental Perspective 271

    The Other Side of Morality: Development of Aggression 272

**Gender Typing** 276

    Gender-Stereotyped Beliefs and Behavior 276

    Biological Influences on Gender Typing 277

    Environmental Influences on Gender Typing 277

    Gender Identity 279

    Reducing Gender Stereotyping in Young Children 280

■ **BIOLOGY AND ENVIRONMENT** *Transgender Children* 281

**Child Rearing and Emotional and Social Development** 282

    Styles of Child Rearing 282

    What Makes Authoritative Child Rearing Effective? 283

    Cultural Variations 284

    Child Maltreatment 285

**Summary** 288

**Important Terms and Concepts** 289

**MILESTONES** *Development in Early Childhood* 290

## PART V

### MIDDLE CHILDHOOD: SIX TO ELEVEN YEARS

## chapter 9

### Physical and Cognitive Development in Middle Childhood 292

**PHYSICAL DEVELOPMENT** 294

**Body Growth** 294

**Common Health Problems** 295

    Nutrition 295

    Overweight and Obesity 295

■ **SOCIAL ISSUES: HEALTH** *Family Stressors and Childhood Obesity* 296

    Vision and Hearing 298

    Illnesses 298

    Unintentional Injuries 298

**Motor Development and Play** 299

    Gross-Motor Development 299

    Fine-Motor Development 300

    Sex Differences 301

    Games with Rules 301

    Adult-Organized Youth Sports 301

    Shadows of Our Evolutionary Past 302

    Physical Education 303

**COGNITIVE DEVELOPMENT** 303

**Piaget's Theory: The Concrete Operational Stage** 304

    Concrete Operational Thought 304

    Limitations of Concrete Operational Thought 306

    Follow-Up Research on Concrete Operational Thought 306

    Evaluation of the Concrete Operational Stage 307

**Information Processing** 307

    Executive Function 307

■ **BIOLOGY AND ENVIRONMENT** *Children with Attention-Deficit Hyperactivity Disorder* 309

    Memory Strategies 310

    Knowledge and Memory 311

    Culture, Schooling, and Memory Strategies 311

    The School-Age Child's Theory of Mind 311

    Cognitive Self-Regulation 312

    Applications of Information Processing to Academic Learning 313

**Individual Differences in Mental Development** 314

    Defining and Measuring Intelligence 314

    Other Efforts to Define Intelligence 315

    Explaining Individual and Group Differences in IQ 317

■ **CULTURAL INFLUENCES** *The Flynn Effect: Massive Generational Gains in IQ* 319

**Language Development** 321

    Vocabulary and Grammar 321

    Pragmatics 322

    Learning Two Languages 323

- Learning in School** 324  
 Educational Philosophies 324  
 Teacher–Student Interaction and Grouping Practices 326  
 Teaching Children with Special Needs 326
- **SOCIAL ISSUES: EDUCATION** *Magnet Schools: Equal Access to High-Quality Education* 327  
 How Well Educated Are U.S. Children? 329
- Summary** 331
- Important Terms and Concepts** 333

## chapter 10

### Emotional and Social Development in Middle Childhood 334

- Erikson’s Theory: Industry versus Inferiority** 336
- Self-Understanding** 336  
 Self-Concept 336  
 Self-Esteem 337  
 Influences on Self-Esteem 337
- Emotional Development** 341  
 Self-Conscious Emotions 341  
 Emotional Understanding 341  
 Emotional Self-Regulation 342
- Moral Development** 342  
 Moral and Social-Conventional Understanding 343  
 Understanding Individual Rights 343  
 Culture and Moral Understanding 344  
 Understanding Diversity and Inequality 344
- Peer Relations** 345  
 Peer Groups 346  
 Friendships 346  
 Peer Acceptance 347
- **BIOLOGY AND ENVIRONMENT** *Bullies and Their Victims* 349
- Gender Typing** 350  
 Gender-Stereotyped Beliefs 350  
 Gender Identity and Behavior 350
- Family Influences** 351  
 Parent–Child Relationships 351  
 Siblings 352  
 Only Children 352  
 Divorce 353  
 Blended Families 355

# A Personal Note to Students

---

My more than 30 years of teaching human development have brought me in contact with thousands of students like you—students with diverse college majors, future goals, interests, and needs. Some are affiliated with my own field, psychology, but many come from other related fields—education, sociology, anthropology, family studies, biology, social service, and nursing, to name just a few. Each semester, my students’ aspirations have proved to be as varied as their fields of study. Many look toward careers in applied work—counseling, caregiving, nursing, social work, school psychology, and program administration. Some plan to teach, and a few want to do research. Most hope someday to become parents, whereas others are already parents who come with a desire to better understand and rear their children. And almost all arrive with a deep curiosity about how they themselves developed from tiny infants into the complex human beings they are today.

My goal in preparing this seventh edition of *Development Through the Lifespan* is to provide a textbook that meets the instructional goals of your course as well as your personal interests and needs. To achieve these objectives, I have grounded this book in a carefully selected body of classic and current theory and research. In addition, the text highlights the lifespan perspective on development and the interwoven contributions of biology and environment to the developing person. It also illustrates commonalities and differences among ethnic groups and cultures and discusses the broader social contexts in which we develop. I have provided a unique pedagogical program that will assist you in mastering information, integrating various aspects of development, critically examining controversial issues, applying what you have learned, and relating the information to your own life.

I hope that learning about human development will be as rewarding for you as I have found it over the years. I would like to know what you think about both the field of human development and this book. I welcome your comments; please feel free to send them to me at [berklifespandevelopment@gmail.com](mailto:berklifespandevelopment@gmail.com).

*Laura E. Berk*

# Preface for Instructors

---

My decision to write *Development Through the Lifespan* was inspired by a wealth of professional and personal experiences. First and foremost were the interests and concerns of hundreds of students of human development with whom I have worked in over three decades of college teaching. Each semester, their insights and questions have revealed how an understanding of any single period of development is enriched by an appreciation of the entire lifespan. Second, as I moved through adult development myself, I began to think more intently about factors that have shaped and reshaped my own life course—family, friends, mentors, co-workers, community, and larger society. My career well-established, my marriage having stood the test of time, and my children launched into their adult lives, I felt that a deeper grasp of these multiple, interacting influences would help me better appreciate where I had been and where I would be going in the years ahead. I was also convinced that such knowledge could contribute to my becoming a better teacher, scholar, family member, and citizen. And because teaching has been so central and gratifying to my work life, I wanted to bring to others a personally meaningful understanding of lifespan development.

The years since *Development Through the Lifespan* first appeared have been a period of unprecedented expansion and change in theory and research. This seventh edition represents these rapidly transforming aspects of the field, with a wealth of new content and teaching tools:

- *Diverse pathways of change are highlighted.* Investigators have reached broad consensus that variations in biological makeup and everyday tasks lead to wide individual differences in paths of change and resulting competencies. This edition pays more attention to variability in development and to recent theories—including ecological, sociocultural, dynamic systems, and epigenesis—that attempt to explain it. Multicultural and cross-cultural findings, including international comparisons, are enhanced throughout the text. Biology and Environment and Cultural Influences boxes also accentuate the theme of diversity in development.
- *The lifespan perspective is emphasized.* As in previous editions, the lifespan perspective—development as lifelong, multidimensional, multidirectional, plastic, and embedded in multiple contexts—continues to serve as a unifying approach to understanding human change and is woven thoroughly into the text.
- *The complex bidirectional relationship between biology and environment is given greater attention.* Accumulating evidence on development of the brain, motor skills, cognitive and language competencies, temperament and personality, emotional and social understanding, and developmental problems underscores the way biological factors emerge in, are modified by, and share power with experience. The interconnection between biology and environment is integral to the lifespan perspective and is revisited throughout the text narrative and in the Biology and Environment boxes with new and updated topics.

- *Inclusion of interdisciplinary research is expanded.* The move toward viewing thoughts, feelings, and behavior as an integrated whole, affected by a wide array of influences in biology, social context, and culture, has motivated developmental researchers to strengthen their ties with other fields of psychology and with other disciplines. Topics and findings included in this edition increasingly reflect the contributions of educational psychology, social psychology, health psychology, clinical psychology, neurobiology, pediatrics, geriatrics, sociology, anthropology, social service, and other fields.
- *Links among theory, research, and applications are strengthened.* As researchers intensify their efforts to generate findings relevant to real-life situations, I have placed greater weight on social policy issues and sound theory- and research-based applications. Further applications are provided in the Applying What We Know tables, which give students concrete ways of building bridges between their learning and the real world.
- *The role of active student learning is made more explicit.* Ask Yourself questions at the end of most major sections have been revised to promote three approaches to engaging with the subject matter—*Connect*, *Apply*, and *Reflect*. This feature assists students in thinking about what they have learned from multiple vantage points. The *Look and Listen* feature asks students to observe what real children, adolescents, and adults say and do; speak with them or with professionals invested in their well-being; and inquire into community programs and practices that influence lifespan development. In addition, highlighting of key terms within the text narrative reinforces student learning in context.

## TEXT PHILOSOPHY

The basic approach of this book has been shaped by my own professional and personal history as a teacher, researcher, and parent. It consists of seven philosophical ingredients that I regard as essential for students to emerge from a course with a thorough understanding of lifespan development. Each theme is woven into every chapter:

1. **An understanding of the diverse array of theories in the field and the strengths and shortcomings of each.** The first chapter begins by emphasizing that only knowledge of multiple theories can do justice to the richness of human development. As I take up each age period and domain of development, I present a variety of theoretical perspectives, indicate how each highlights previously overlooked aspects of development, and discuss research that evaluates it. Consideration of contrasting theories also serves as the context for an even-handed analysis of many controversial issues.
2. **A grasp of the lifespan perspective as an integrative approach to development.** I introduce the lifespan perspective

as an organizing framework in the first chapter and refer to and illustrate its assumptions throughout the text, in an effort to help students construct an overall vision of development from conception to death.

3. **Knowledge of both the sequence of human development and the processes that underlie it.** Students are provided with discussion of the organized sequence of development along with processes of change. An understanding of process—how complex combinations of biological, psychological, and environmental factors produce development—has been the focus of most recent research. Accordingly, the text reflects this emphasis. But new information about the timetable of change has also emerged. In many ways, the very young and the old have proved to be more competent than they were believed to be in the past. In addition, many milestones of adult development, such as finishing formal education, entering a career, getting married, having children, and retiring, have become far less predictable. Current evidence on the sequence and timing of development, along with its implications for process, is presented for all periods of the lifespan.
4. **An appreciation of the impact of context and culture on human development.** A wealth of research indicates that people live in rich physical and social contexts that affect all domains of development. Throughout the book, students travel to distant parts of the world as I review a growing body of cross-cultural evidence. The text narrative also discusses many findings on socioeconomically and ethnically diverse people within the United States. Furthermore, the impact of historical time period and cohort membership receives continuous attention. In this vein, gender issues—the distinctive but continually evolving experiences, roles, and life paths of males and females—are granted substantial emphasis. Besides highlighting the effects of immediate settings, such as family, neighborhood, and school, I make a concerted effort to underscore the influence of larger social structures—societal values, laws, and government policies and programs—on lifelong well-being.
5. **An understanding of the joint contributions of biology and environment to development.** The field recognizes more powerfully than ever before the joint roles of hereditary/constitutional and environmental factors—that these contributions to development combine in complex ways and cannot be separated in a simple manner. Numerous examples of how biological dispositions can be maintained as well as transformed by social contexts are presented throughout the book.
6. **A sense of the interdependency of all domains of development—physical, cognitive, emotional, and social.** Every chapter emphasizes an integrated approach to human development. I show how physical, cognitive, emotional, and social development are interwoven. Within the text narrative, and in the Ask Yourself questions at the end of major sections, students are referred to other sections of the book to deepen their grasp of relationships among various aspects of change.

7. **An appreciation of the interrelatedness of theory, research, and applications.** Throughout this book, I emphasize that theories of human development and the research stimulated by them provide the foundation for sound, effective practices with children, adolescents, and adults. The link among theory, research, and applications is reinforced by an organizational format in which theory and research are presented first, followed by practical implications. In addition, a current focus in the field—harnessing knowledge of human development to shape social policies that support human needs throughout the lifespan—is reflected in every chapter. The text addresses the current condition of children, adolescents, and adults in the United States and elsewhere in the world and shows how theory and research have combined with public interest to spark successful interventions. Many important applied topics are considered, such as family planning, infant mortality, parental employment and child care, adolescent pregnancy and parenthood, domestic violence, exercise and adult health, religiosity and well-being, lifelong learning, grandparents rearing grandchildren, caring for aging adults with dementia, adjustment to retirement, successful aging, and palliative care for the dying.

## TEXT ORGANIZATION

I have chosen a chronological organization for *Development Through the Lifespan*. The book begins with an introductory chapter that describes the scientific history of the field, influential theories, and research strategies. It is followed by two chapters on foundations of development. Chapter 2 combines an overview of genetic and environmental contexts into a single integrated discussion of these multifaceted influences on development. Chapter 3 is devoted to prenatal development, birth, and the newborn baby. With these foundations, students are ready to look closely at seven major age periods: infancy and toddlerhood (Chapters 4, 5, and 6), early childhood (Chapters 7 and 8), middle childhood (Chapters 9 and 10), adolescence (Chapters 11 and 12), early adulthood (Chapters 13 and 14), middle adulthood (Chapters 15 and 16), and late adulthood (Chapters 17 and 18). Topical chapters within each chronological division cover physical development, cognitive development, and emotional and social development. The book concludes with a chapter on death, dying, and bereavement (Chapter 19).

The chronological approach assists students in thoroughly understanding each age period. It also eases the task of integrating the various domains of development because each is discussed in close proximity. At the same time, a chronologically organized book requires that theories covering several age periods be presented piecemeal. This creates a challenge for students, who must link the various parts together. To assist with this task, I frequently remind students of important earlier achievements before discussing new developments, referring back to related sections with page references. Also, chapters or sections devoted to the same topic (for example, cognitive development) are similarly organized, making it easier for students to draw connections across age periods and construct an overall view of developmental change.

## NEW COVERAGE IN THE SEVENTH EDITION

Lifespan development is a fascinating and ever-changing field of study, with constantly emerging new discoveries and refinements in existing knowledge. The seventh edition represents this burgeoning contemporary literature, with over 2,300 new citations. Cutting-edge topics throughout the text underscore the book's major themes. Here is a sampling:

**CHAPTER 1:** Introduction to the developmental systems approach, as illustrated by the lifespan perspective • Updated Cultural Influences box on baby boomers reshaping the life course • Updated Social Issues: Health box on the impact of family chaos on parents' and children's well-being • Revised section on developmental neuroscience, with special attention to developmental social neuroscience • Updated examples of research strategies, including naturalistic observation, case studies, and sequential design • Inclusion of children's assent as part of informed consent guidelines for protection of human subjects

**CHAPTER 2:** Updated discussion of gene–gene interactions, including the distinction between protein-coding genes and regulator genes, which greatly complicate genetic influences • New evidence on older paternal age and increased risk of DNA mutations contributing to psychological disorders, including autism and schizophrenia • Updated Social Issues: Health box on the pros and cons of reproductive technologies • Recent findings on neighborhood influences on physical and mental health • New section on contributions of schooling to development and life chances, with special attention to SES differences • Expanded attention to the role of ethnic minority extended families in promoting resilience in the face of prejudice and economic deprivation • Updated sections on public policies and development, including current statistics on the condition of children, adolescents, and older adults in the United States compared with other Western nations • Enhanced discussion of gene–environment interaction, with illustrative new research findings • Expanded section on epigenesis, including the role of methylation along with new examples of environmental influences on gene expression • New Biology and Environment box on epigenetic transmission of maternal stress to children

**CHAPTER 3:** Enhanced attention to development during the prenatal period, including brain growth, sensory capacities, and embryonic and fetal behavior • Expanded and updated consideration of a wide range of teratogens • New evidence on the long-term consequences of severe emotional stress during pregnancy • Updated Social Issues: Health box on the Nurse–Family Partnership—reducing maternal stress and enhancing child development through social support • New statistics and research on benefits and risks of medical interventions during childbirth • New findings on risks of late preterm birth—as little as 1 or 2 weeks early • Updated research on interventions for preterm and low-birth-weight infants, including kangaroo care and recordings of

the mother's voice and heartbeat • Expanded and updated Social Issues: Health box on health care and other policies for parents and newborn babies, including cross-national infant mortality rates and the importance of generous parental leave • Updated findings on hormonal changes in both mothers and fathers around the time of birth, and in foster and adoptive mothers, that facilitate effective caregiving • Revised Biology and Environment box on sudden infant death syndrome, including the importance of public education about safe sleep environments and other protective measures

**CHAPTER 4:** Updated discussion of advances in brain development, with special attention to the prefrontal cortex • Revised Biology and Environment box on early brain plasticity, based on research on brain-damaged children and adults • New evidence on infant sleep, including contributions of bedtime routines to sleep quality • Enhanced attention to cultural influences on infant sleep, including updated Cultural Influences box addressing parent–infant cosleeping and bedsharing • New findings on long-term consequences of malnutrition in infancy and toddlerhood • Updated discussion of the controversy surrounding newborns' capacity to imitate • Updated evidence on how environmental factors, including caregiving practices and the baby's physical surroundings, contribute to motor development • New findings on implications of infants' capacity to analyze the speech stream for later language progress • Enhanced discussion of the impact of crawling and walking experience on perceptual and cognitive development • Expanded and updated section on intermodal perception, including its contributions to diverse aspects of learning

**CHAPTER 5:** New research on analogical problem solving in infants and toddlers • Updated evidence on toddlers' grasp of pictures and videos as symbols, including experiences that enhance symbolic understanding • New research on infants' numerical knowledge • Revised and enhanced introduction to the concept of executive function • New evidence on the similarity of infant and toddler memory processing to that of older children and adults • New research on cultural variations in scaffolding infant and toddler learning • New evidence on the importance of sustained high-quality child care from infancy through the preschool years for cognitive, language, literacy, and math progress at kindergarten entry • Updated findings on infants' participation in imitative exchanges and joint attention, revealing their developing capacity to engage in cooperative processes necessary for effective communication • Enhanced attention to SES differences in early vocabulary development as a predictor of vocabulary size at kindergarten entry, with implications for literacy skills and school success • New evidence highlighting the importance of a responsive adult for early language development, in both real-life and video contexts

**CHAPTER 6:** New research on cultural variations in development of emotional self-regulation • New findings on factors influencing the low to moderate stability of temperament, including parenting and young children's developing capacity

for effortful control • Revised section on genetic and environmental influences on temperament, with special attention to ethnic and gender differences • New section on temperamental differences in susceptibility to the effects of good and poor parenting, highlighting evidence on the short 5-HTTLPR gene • Updated research on cultural variations in views of sensitive caregiving, with implications for attachment security • New findings on the joint contributions of infant genotype, temperament, and parenting to disorganized/disoriented attachment, with special attention to the short 5-HTTLPR and DRD4-7 repeat gene • New illustration of interventions that promote attachment security by teaching parents to interact sensitively with difficult-to-care-for babies • New evidence on contributions of fathers' involvement in caregiving to attachment security and to cognitive, emotional, and social competence • New research on the implications of infant-caregiver attachment for later development, with special emphasis on continuity of caregiving • Updated research on cultural variations in early self-development

**CHAPTER 7:** Updated consideration of advances in brain development in early childhood, with enhanced attention to the prefrontal cortex and executive function • Updated statistics and research on the health status of young children, including tooth decay and childhood immunizations • New evidence on parenting practices and young children's unintentional injuries • New Cultural Influences box addressing why children from Asian cultures are advanced in drawing progress and artistic creativity • Updated evidence on early childhood categorization, highlighting cultural differences • New section on development of executive function in early childhood, with evidence on the facilitating role of parental sensitivity and scaffolding • Updated discussion of development of memory in early childhood, including the distinction between episodic memory and semantic memory • New evidence on cognitive attainments and social experiences that contribute to young children's mastery of false belief • Updated Biology and Environment box on autism and theory of mind • Revised section on strengthening preschool intervention for economically disadvantaged children, including findings on Head Start REDI • Updated discussion of educational media, including effects on cognitive development and academic learning

**CHAPTER 8:** Recent findings on development of emotional understanding and emotional self-regulation in early childhood • New research on the influence of parents' elaborative reminiscing on self-concept and emotional understanding • New evidence addressing contributions of sociodramatic and rough-and-tumble play to young children's emotional and social development • Expanded and updated section on contributions of early childhood peer relations to school readiness and academic performance • New research on corporal punishment and children's adjustment, with special attention to children at high genetic risk for behavior problems • Updated Cultural Influences box on ethnic differences in the consequences of physical punishment • Recent research on moral understanding in early childhood, including contributions of language, theory of mind, peer and

sibling experiences, and parenting • Expanded discussion of media exposure and young children's aggression • New Biology and Environment box on transgender children • New findings on early intervention to prevent child maltreatment, with special attention to Healthy Families America home visiting program

**CHAPTER 9:** New Social Issues: Health box on family stressors and childhood obesity • New evidence on contributions of children's physical fitness to executive function, memory, and academic achievement • Expanded attention to informal, child-organized games, including SES and cultural variations • Updated research on school-age children's spatial reasoning, focusing on cognitive maps of large-scale spaces • New section on gains in executive function in middle childhood, including related changes in the brain, implications for academic learning, and interventions that train executive function in children with learning difficulties • Updated evidence on the school-age child's theory of mind, with special attention to recursive thought • New Cultural Influences box on the Flynn effect, dramatic gains in IQ from one generation to the next • Updated findings on reducing cultural bias in testing through dynamic assessment and interventions that counter the negative impact of stereotype threat • Expanded discussion of the diverse cognitive benefits of bilingualism • Updated section on U.S. academic achievement in international perspective

**CHAPTER 10:** Updated discussion of cultural influences on self-esteem, including gender and ethnic variations • New evidence addressing effects of person praise and process praise on children's mastery orientation • New section on culture and moral understanding • Enhanced consideration of racial and ethnic prejudice in school-age children, including effective ways to reduce prejudice • Revised and updated Biology and Environment box on bullies and their victims, with special attention to cyberbullying • Updated discussion of school-age children's gender-stereotyped beliefs, including stereotypes about achievement • Expanded coverage of effects of maternal and dual-earner employment on child development • Revised and updated Cultural Influences box on the impact of ethnic and political violence on children • Updated evidence on child sexual abuse, including long-term consequences for physical and psychological health • Enhanced discussion of resilience in middle childhood, including research on social and emotional learning interventions

**CHAPTER 11:** Updated statistics on physical activity levels among U.S. adolescents • New research on adolescent brain development, with implications for adolescent risk-taking and susceptibility to peer influence • New evidence on effects of pubertal timing on adjustment • Recent research on nutritional needs and dietary choices of U.S. adolescents • Expanded discussion of adolescent sexuality, with new evidence on factors contributing to early sexual activity • New research on substance use and abuse, including the Strong African American Families (SAAF) program, aimed at reducing drug experimentation • Updated discussion of sex differences in mental abilities, including current

evidence on reading, writing, and math achievement • Expanded discussion of school transitions, with new findings on achievement of students in K–8 versus middle schools • Updated Social Issues: Education box on effects of media multitasking on learning, with new evidence on consequences for executive function • Expanded discussion of high school students' part-time work and implications for academic and social adjustment

**CHAPTER 12:** Expanded consideration of influences on adolescents' self-esteem, including parents, peers, and larger social environment • New research on the process of identity development, along with personal and social influences • Updated evidence on adolescents' capacity to integrate moral, social-conventional, and personal concerns • Enhanced consideration of parental, peer, and school influences on moral maturity • Enhanced discussion of parent–adolescent relationships and development of autonomy, including cultural variations • New evidence on contributions of sibling relationships to adolescent adjustment • New research on gender differences in friendship quality among ethnic minority youths • Expanded and updated section on teenagers' online communication with friends, including consequences for friendship quality and social adjustment • Updated evidence on adolescent depression, addressing the combined influence of heredity, pubertal hormones, and family, peer, and life-event influences, with special attention to gender differences • New research on family, school, and neighborhood contributions to delinquency

**CHAPTER 13:** Updated Biology and Environment box on telomere length as a marker of the impact of life circumstances on biological aging • New statistics on overweight and obesity in adulthood, including international comparisons, variations among U.S. ethnic groups, and approaches to treatment • New research on substance abuse in early adulthood, including sex differences in progression to alcohol dependence • New findings on sexual attitudes and behavior among young adults, including Internet dating, sex differences in number of lifetime partners, sex without relationship commitment on U.S. college campuses, same-sex relationships, and implications of sexual activity for life satisfaction • Discussion of generational differences in acceptance of same-sex marriage, including high acceptance by Millennials • Updated section on risk of sexually transmitted infections (STIs) in early adulthood, with special attention to HIV/AIDS • Revised and updated evidence on sexual coercion • Updated evidence on cognitive ingredients of creativity, including reduced inhibition of information that, at first glance, appears irrelevant • New Social Issues: Education box on the importance of academic engagement in college for successful transition to the labor market • Enhanced consideration of women's progress in choosing male-dominated careers, with special attention to college women talented in math and science

**CHAPTER 14:** New evidence on emerging adults' identity development, including cultural variations in timing of identity achievement • Updated section on religion and spirituality among

emerging adults, with implications for psychological adjustment • New findings on forms of love, with special attention to compassionate love and contributions of commitment to lasting intimate relationships • Updated research on cultural variations in experience of love, including arranged-marriage couples whose love grew over time • New evidence on lesbian and gay intimate relationships • Updated discussion of the challenges and rewards of parenthood • Recent findings on cohabitation, with special attention to factors linked to relationship persistence and dissolution • New research on gay and lesbian parents and their children's development • Updated findings on the challenges experienced by women who pursue male-dominated careers • Enhanced consideration of gender variations in career development, including factors contributing to the widespread gender pay gap and to differences in career advancement

**CHAPTER 15:** Updated Biology and Environment box on anti-aging effects of dietary calorie restriction • New evidence on physical and mental symptoms associated with the climacteric and menopause • Updated evidence on sexual activity of midlife cohabiting and married couples • Updated findings on gender bias in medical treatment of women for heart attacks • New research on developmental trends in Type A behavior • New findings on regular physical exercise and reduced mortality risk throughout adulthood, along with approaches to increasing midlife physical activity • New Social Issues: Health box on mental health benefits of modest lifetime exposure to adversity • New section on executive function in midlife, focusing on declines in working memory, inhibition, and flexible shifting of attention, and on middle-aged adults' compensatory strategies • Revised and updated section on practical problem solving and expertise in middle adulthood

**CHAPTER 16:** New evidence on the relationship of midlife generativity to psychological adjustment, including civic, political, and religious engagement • Updated research on life regrets and midlife psychological well-being • Enhanced Biology and Environment box on factors that promote psychological well-being in midlife, with new evidence on the link between physical activity and improved executive function • Discussion of the dramatic rise in death rates due to suicide and drug and alcohol abuse among U.S. middle-aged white men • Revised and updated section on gender identity, with special attention to cohort effects on the midlife rise in androgyny • New research on marriage and divorce in middle adulthood • Updated evidence on SES variations in support provided by middle-aged parents to their adult children • New findings on cultural variations in middle-aged children caring for aging parents • Recent research on midlife sibling relationships, with special attention to the persisting influence of parental favoritism • New evidence on gender and SES variations in the midlife rise in job satisfaction

**CHAPTER 17:** New evidence on the relationship of visual and hearing impairments to cognitive functioning • Updated consideration of assistive technology for older people with disabilities •

Enhanced discussion of the impact of negative stereotypes of aging on older adults' physical, cognitive, and emotional functioning • Updated evidence on sexuality in late adulthood • New findings on risk and protective factors for Alzheimer's disease, including the role of epigenetic processes • Updated findings on the associative memory deficit in late life • New findings on the reminiscence bump in autobiographical recall • Enhanced discussion of language processing, with special attention to aging adults' narrative competence • Attention to the adverse impact of "elderspeak," simplified, patronizing language often directed at aging adults • Updated discussion of cognitive interventions aimed at older adults, including those directed at improving executive function • Revised and updated Social Issues: Education box on how intensive training in the art of acting enhances cognitive functioning in aging adults

**CHAPTER 18:** New section on the positivity effect, older adults' bias toward emotionally positive information, plus expanded discussion of late-life expertise in emotional self-regulation • Updated findings on spirituality and religiosity in late adulthood, including aspects of religious involvement that enhance older adults' psychological well-being • New research on contributions of personal control to life satisfaction • New evidence on socioemotional selectivity theory, including age-related change in closeness of social partners • Updated discussion of assisted living, including variations in quality of U.S. facilities, with implications for aging adults with limited financial resources • Revised and updated section on late-life marriage, with special attention

to diversity in marital satisfaction • New evidence on lesbian and gay older couples, including advantages of legally recognized marriage for physical and mental health • Updated research on late-life divorce, remarriage, and cohabitation, along with the growing number of couples described as living apart together • Enhanced and updated discussion of elder abuse, with updated statistics on U.S. incidence, new evidence on traits of perpetrators, and physical and mental health consequences for victims • New Biology and Environment box on Experience Corps, illustrating the benefits of volunteer service for older adults' physical and mental health

**CHAPTER 19:** Updated section on children's understanding of death including cultural variations in parents' candidness in discussing death with children • Attention to the role of forgiveness in relieving distress and inducing a sense of life completion among the terminally ill • Enhanced discussion of patients' and family members' experiences with dying at home • Updated evidence on the diverse benefits of hospice care for dying patients and family members • New findings on the success of music vigils in reducing pain and promoting psychological well-being among dying patients • Revised sections on medical aid-in-dying and voluntary euthanasia, including ethical issues and current public and physician opinion • Findings indicating that the typical response to loss of a loved one is resilience • Enhanced consideration of gender differences in grieving, with special attention to parents who have lost a child • Revised and updated section on death education

# PEDAGOGICAL FEATURES

Maintaining a highly accessible writing style—one that is lucid and engaging without being simplistic—continues to be one of my major goals. I frequently converse with students, encouraging them to relate what they read to their own lives. In doing so, I aim to make the study of human development involving and pleasurable.

## Chapter Introductions and Vignettes

To provide a helpful preview of chapter content, I include an outline and overview in each chapter introduction. To help students construct a clear image of development and to enliven the text narrative, each chronological age division is unified by case examples woven throughout that set of chapters. For example, the middle childhood section highlights the experiences and concerns of 10-year-old Joey; 8-year-old Lizzie; their divorced parents, Rena and Drake; and their classmates. In the chapters on late adulthood, students get to know Walt and Ruth, a vibrant retired couple, along with Walt's older brother, Dick, and his wife, Goldie, and Ruth's sister, Ida, a victim of Alzheimer's disease. Besides a set of main characters who bring unity to each age period, many additional vignettes offer vivid examples of development and diversity among children, adolescents, and adults.

### chapter 8

## Emotional and Social Development in Early Childhood

During the preschool years, children make great strides in understanding the thoughts and feelings of others, and they build on these skills as they form first friendships—special relationships marked by attachment and common interests.

### What's ahead in chapter 8

- Erikson's Theory: Initiative versus Guilt Self-Understanding**  
Foundations of Self-Concept • Emergence of Self-Esteem
- CULTURAL INFLUENCES** Cultural Variations in Personal Storytelling: Implications for Early Self-Concept
- Emotional Development**  
Understanding Emotion • Emotional Self-Regulation • Self-Conscious Emotions • Empathy and Sympathy
- Peer Relations**  
Advances in Peer Sociability • First Friendships • Peer Relations and School Readiness • Parental Influences on Early Peer Relations
- Foundations of Morality and Aggression**  
The Psychoanalytic Perspective • Social Learning Theory • The Cognitive-Developmental Perspective • The Other Side of Morality: Development of Aggression
- CULTURAL INFLUENCES** Ethnic Differences in the Consequences of Physical Punishment
- Gender Typing**  
Gender-Stereotyped Beliefs and Behaviors • Biological Influences on Gender Typing • Environmental Influences on Gender Typing • Gender Identity • Reducing Gender Stereotyping in Young Children
- BIOLOGY AND ENVIRONMENT**  
Transgender Children
- Child Rearing and Emotional and Social Development**  
Styles of Child Rearing • What Makes Authoritative Child Rearing Effective? • Cultural Variations • Child Maltreatment

As the children in Leslie's classroom moved through the preschool years, their personalities took on clearer definition. By age 3, they voiced firm likes and dislikes as well as new ideas about themselves. "Stop bothering me," Sammy said to Mark, who had reached for Sammy's beanbag as Sammy aimed it toward the mouth of a large clown face. "See, I'm great at this game," Sammy announced with confidence, an attitude that kept him trying, even though he missed most of the throws.

The children's conversations also revealed early notions about morality. Often they combined statements about right and wrong with forceful attempts to defend their own desires. "You're 'posed to share,'" stated Mark, grabbing the beanbag out of Sammy's hand.

"I was here first! Gimme it back," demanded Sammy, pushing Mark. The two boys struggled until Leslie intervened, provided an extra set of beanbags, and showed them how they could both play.

As the interaction between Sammy and Mark reveals, preschoolers quickly become complex social beings. Young children argue, grab, and push, but cooperative exchanges are far more frequent. Between ages 2 and 6, first friendships form, in which children converse, act out complementary roles, and learn that their own desires for companionship and toys are best met when they consider others' needs and interests.

The children's developing understanding of their social world was especially apparent in their growing attention to the dividing line between male and female. While Priti and Karen cared for a sick baby doll in the housekeeping area, Sammy, Vance, and Mark transformed the block corner into a busy intersection. "Green light, go!" shouted police officer Sammy as Vance and Mark pushed large wooden cars and trucks across the floor. Already, the children preferred peers of their own gender, and their play themes mirrored their culture's gender stereotypes.

This chapter is devoted to the many facets of early childhood emotional and social development. We begin with Erik Erikson's theory, which provides an overview of personality change in the preschool years. Then we consider children's concepts of themselves, their insights into their social and moral worlds, their gender typing, and their increasing ability to manage their emotional and social behaviors. Finally, we ask, What is effective child rearing? And we discuss the complex conditions that support good parenting or lead it to break down, including the serious and widespread problems of child abuse and neglect.

464 CHAPTER 13 Physical and Cognitive Development in Early Adulthood

---

### Summary / chapter 13

**PHYSICAL DEVELOPMENT**

**Biological Aging Is Under Way in Early Adulthood (p. 438)**

13.1 Describe current theories of biological aging, both at the level of DNA and body cells and at the level of tissues and organs.

- Once body structures reach maximum capacity and efficiency in the teens and twenties, biological aging, or senescence, begins.
- The immune response declines after age 20 because of shrinkage of the thymus gland and increased difficulty coping with physical and psychological stress.
- Women's reproductive capacity declines with age due to reduced quality and quantity of ova. In men, semen volume and sperm motility decrease gradually after age 35, and the percentage of abnormal sperm rises.

**Health and Fitness (p. 444)**

13.3 Describe the influence of sex, nutrition, and exercise on health, and discuss obesity in adulthood.

- Health inequalities associated with SES increase in adulthood. Health-related circumstances and habits underlie these disparities.
- Sedentary lifestyles and diets high in sugar and fat have contributed to the U.S. overweight and obesity epidemic. Excess weight is associated with serious health problems, social discrimination, and early death.
- Some weight gain in adulthood reflects a decrease in basal metabolic rate (BMR), but many young adults add excess weight. Effective treatment includes a nutritious diet low in calories plus regular exercise, recording of food intake and body weight, social support, and teaching problem-solving skills.
- Regular exercise reduces body fat, builds muscle, fosters resistance to disease, and enhances cognitive functioning and psychological well-being.

13.4 What are the most commonly abused substances, and what health risks do they pose?

- Tobacco, marijuana, and alcohol are the most commonly abused substances. Cigarette smokers, most of whom began before age 21, are at increased risk for many health problems, including decline in bone mass, heart attack, stroke, and numerous cancers.
- About one-third of heavy drinkers suffer from alcoholism, to which both heredity and environment contribute. Alcohol is implicated in liver and cardiovascular disease, certain cancers and other physical disorders, motor vehicle fatalities, crime, and sexual coercion.

13.5 Describe sexual attitudes and behavior of young adults, and discuss sexually transmitted infections and sexual coercion.

- Most adults are less sexually active than media images suggest, but they display a wider range of sexual choices and lifestyles and have had more sexual partners than earlier generations. The Internet has become a popular way to initiate relationships.
- Adults in committed relationships report high satisfaction with their sex lives. Only a minority report persistent sexual problems—difficulties linked to biological factors and to low SES and psychological stress.

Attitudes toward same-sex couples have become more accepting. Same-sex partners, like heterosexual partners, tend to be similar in education and background and more satisfied in committed relationships.

Sexually transmitted infections (STIs) continue to be prevalent throughout the twenties; women are at great risk for lasting health consequences. AIDS, the most deadly STI, is spreading most rapidly through men having sex with men and through heterosexual contact in poverty-stricken minority groups.

**Physical Changes (p. 440)**

13.2 Describe the physical changes of aging, paying special attention to the cardiovascular and respiratory systems, motor performance, the immune system, and reproductive capacity.

- Gradual physical changes take place in early adulthood and later accelerate. Declines in heart and lung performance are evident during exercise. Heart disease is a leading cause of death in adults, although it has decreased since the mid-twentieth century due to lifestyle changes and medical advances.

## End-of-Chapter Summaries

Comprehensive end-of-chapter summaries, organized according to the major divisions of each chapter and highlighting important terms, remind students of key points in the text discussion. Learning objectives are included in the summary to encourage active study.

**LOOK and LISTEN**

While watching a parent and infant playing, list instances of parental intermodal stimulation and communication. What is the baby likely learning about people, objects, or language from each intermodal experience?

**LOOK and LISTEN**

While watching a parent and infant playing, list instances of parental intermodal stimulation and communication. What is the baby likely learning about people, objects, or language from each intermodal experience?

In sum, intermodal perception fosters all aspects of psychological development. When caregivers provide more concurrent visual, auditory, and tactile information, babies process more information and learn faster (Bahrick, 2010). Intermodal perception is yet another fundamental capacity that assists infants in their active efforts to build an orderly, predictable world.

**Understanding Perceptual Development**

Now that we have reviewed the development of infant perceptual capacities, how can we...

But even though they know better, many parents and children behave in ways that compromise safety. About 27 percent of U.S. parents fail to place their children in car safety seats, and nearly 75 percent of infant seats and 40 percent of child booster seats are improperly used (Macy et al., 2015; Safe Kids Worldwide, 2011). American parents, especially those of the high value they place on individual rights and personal freedom...

Furthermore, many parents overestimate young children's knowledge of hazards. And when parents teach safety to preschoolers, they frequently fail to explain the basis for the rules—despite evidence that explanations enhance children's retention, understanding, and compliance (Morrongiello, Ouellet, & Littlejohn, 2004; Morrongiello et al., 2014). Even when well-learned rules, preschoolers need supervision to ensure that they comply (Morrongiello, Midgett, & Shields, 2001).

Interventions aimed at parents that highlight risk factors and that model and reinforce safety practices are effective in reducing home hazards and childhood injuries (Kendrick et al., 2008). Attention must also be paid to family conditions that can prevent childhood injury: relieving crowding in the home, providing social supports to ease parental stress, and teaching parents to use effective discipline—a topic we will take up in Chapter 8.

**Ask yourself**

**CONNECT** Using research on handedness, malnutrition, or unintentional injuries, show how physical growth and health in early childhood result from a complex interplay between heredity and environment.

**APPLY** One day, Leslie prepared a new snack to serve at preschool. Her childer stuffed with ricotta cheese. The first time she served it, few children touched it. How can Leslie encourage her students to accept the snack? What tactics should she avoid?

**REFLECT** Ask a parent or other family member whether, as a preschooler, you were a picky eater, suffered from many infectious diseases, or sustained any serious injuries. What factors might have been responsible?

**Motor Development**

7.4 Cite major milestones of gross- and fine-motor development with factors that affect motor progress in early childhood.

Observe several 2- to 6-year-old children play in a neighborhood preschool, or child-care center. Note how many of the children's motor skills occur in the context of play, and how many occur in the context of more structured activities of toddlerhood.

**Motor Development**

7.4 Cite major milestones of gross- and fine-motor development with factors that affect motor progress in early childhood.

Observe several 2- to 6-year-old children play in a neighborhood preschool, or child-care center. Note how many of the children's motor skills occur in the context of play, and how many occur in the context of more structured activities of toddlerhood.

**Look and Listen**

This active-learning feature presents students with opportunities to observe what real children, adolescents, and adults say and do; speak with them or with professionals invested in their well-being; and inquire into community programs and practices that influence development. “Look and Listen” experiences are tied to relevant text sections, with the goal of making the study of development more authentic and meaningful.

**Ask Yourself Questions**

Active engagement with the subject matter is also supported by study questions at the end of most major sections. Three types of questions prompt students to think about human development in diverse ways: **Connect** questions help students build an image of the whole person by integrating what they have learned across age periods and domains of development. **Apply** questions encourage application of knowledge to controversial issues and problems faced by children, adolescents, adults, and professionals who work with them. **Reflect** questions personalize study of human development by asking students to reflect on their own development and life experiences.

**Learning Objectives**

New to this edition, learning objectives appear below each main heading, guiding students’ reading and study.

**Three Types of Thematic Boxes**

Thematic boxes accentuate the philosophical themes of this book:

**Social Issues** boxes discuss the impact of social conditions on children, adolescents, and adults, and emphasize the need for sensitive social policies to ensure their well-being. They are divided into two types: **Social Issues: Education** boxes focus on home, school, and community influences on learning—for example, *Magnet Schools: Equal Access to High-Quality Education*, *Media Multitasking Disrupts Learning*, and *How Important Is Academic Engagement in College for Successful Transition to the Labor Market?*

**CHAPTER 13 Physical and Cognitive Development in Early Adulthood** 461

**Social Issues: Education**

**How Important Is Academic Engagement in College for Successful Transition to the Labor Market?**

**D**o critical thinking, complex reasoning, and written communication—skills designated by educators and employers as crucial for success in the twenty-first century economy—really matter in college graduates’ efforts to secure a satisfying, well-paid job? To find out, researchers gave 1,600 students at 25 U.S. four-year colleges and universities a test of general collegiate learning in the fall of their first year and, again, around the time they graduated (Irem & Rolska, 2014). The students also responded to surveys and in-depth interviews about the meaningfulness of their college experiences. Two years after graduation, they reported on employment outcomes.

Participants’ post-college paths varied widely. Some transitioned successfully to challenging work roles that launched them on a career track. But more than half were underemployed (in jobs not requiring a college education) or unemployed. Across institutions varying widely in admission requirements, senior-year collegiate learning scores predicted success at securing jobs requiring bachelor’s level skills, along with student reports that their work was both cognitively challenging and personally fulfilling.

Successful graduates were keenly aware of this link between collegiate learning and post-college success. Ashley, who landed a well-paid job as a program coordinator at a senior center, commented that her college in-class and out-of-class experiences taught her how “to work in groups... to think critically and be able to solve problems [and] to understand different perspectives” (Aram & Rolska, 2014, p. 77). In contrast, students with low college learning scores found it hard to articulate the benefits of their college experiences. After an unsuccessful search for work related to his business degree, Nathan accepted a low-wage job as a delivery driver for a retail chain. Although he graduated with a high grade point average, he mentioned going to lots of parties, could think of little that stood out about his courses, and did not participate in any educationally relevant extracurricular activities.

Like Nathan, most participants relevant little in collegiate learning during their four years of college. Since the 1970s, the time U.S. college students spend studying has declined by half, while the time they devote to socializing and other forms of entertainment has risen dramatically (Brent & Cantwell, 2010). As institutions redefined students as consumers, academic demands receded and grade inflation increased.

Surveys of employers indicate that less than one-fourth of U.S. college graduates enter the labor market with excellent collegiate skills (Fischer, 2013). Clear evidence that critical thinking, complex reasoning, and written communication have substantial labor market payoffs underscores the need for colleges to promote students’ involvement in academics and career-relevant extracurricular experiences, and to upgrade the rigor of their courses.

advisers or professors (Stewart, Lim, & Kim, 2015). At the same time, colleges that do little to help high-risk students, through developmental courses and other support services, have a higher percentage of dropouts.

Beginning to prepare young people in early adolescence with the necessary vision and skills for the twenty-first century

within reach, through a wide array of strategies considered in Chapters 11 and 12.

Once young people enroll in college, reaching out to them, especially during the early weeks and throughout the first year, is crucial. Programs that forge bonds between teachers and students

Social Issues: Health

The Silver Lining in Life's Adversities

Many adults, in recounting a difficult time in their lives, say that ultimately it made them stronger—an outcome confirmed by research. As long as serious adversity is not frequent and overwhelming, it can lead to remarkable personal benefits.

In a study carried out in France, researchers followed a nationally representative sample of 2,000 adults, ranging in age from 18 to 101, for four years (Seery, Holman & Silver, 2010). To assess lifetime exposure to adversity, participants were given a list of 37 negative life events and asked to indicate which ones they had experienced, how often, and the age at which each had occurred. The list focused on serious stressors—for example, violent assault, death of a loved one, severe financial difficulties, divorce, and major disasters such as fire, flood, or earthquake.

activities due to poor physical and mental health), fewer post-traumatic stress symptoms, and greater life satisfaction (see Figure 15.5). Furthermore, people with modest lifetime adversity were less negatively affected by exposure to recent adversity. These outcomes remained after controlling for diverse factors that might influence experiences of adversity, including age, gender, ethnicity, marital status, SES, and so on.

FIGURE 15.5 Relationship of Lifetime Adversity to Mental Health and Life Satisfaction

Biology and Environment

The Tutsi Genocide and Epigenetic Transmission of Maternal Stress to Children

In 1994, in a genocidal rampage committed by members of the Hutu majority against the Tutsi people of Rwanda, nearly 1 million perished within a three-month period. The horror was so extreme that in surveys of Rwandans during the years following the genocide, an estimated 40 to 60 percent reported symptoms of post-traumatic stress disorder (PTSD) (Neugebauer et al., 2009; Schaal et al., 2011). In PTSD, flashbacks, nightmares, and difficulty concentrating lead to intense distress, physical symptoms, and loss of interest in relationships and daily life.

Parental PTSD is a strong predictor of child PTSD (Briere et al., 2009). In both associated with stress responses, blood levels of cortisol, a hormone that our brain produces in response to stress, are elevated in individuals who have experienced trauma.

Might this epigenetic process contribute to parent-to-child transmission of PTSD? To explore this question, researchers identified 50 Tutsi women who had been pregnant during the genocide (Perroud et al., 2014). Half had been directly exposed to the trauma; the other half had not been exposed due to being out of the country at the time. Eighteen years later, the mothers and their adolescent children were assessed for PTSD and depression by trained psychologists. Blood samples from the children were analyzed for methylation of the glucocorticoid receptor gene and assessment of stress-hormone levels (which we discuss further in Chapter 3).

Compared with non-exposed mothers, children of mothers who witnessed the genocidal carnage had higher PTSD and depression symptoms, and higher cortisol levels.

This Rwandan mother gave birth shortly after the Tutsi genocide, nine years later, she continues to suffer from PTSD caused by the brutal experience of her mother, brother, and two sisters in the genocide. Her daughter's PTSD and depression symptoms are linked to her maternal exposure to severe trauma.

Cultural Influences

Cultural Variations in Mourning Behavior

The ceremonies that commemorated Solie's and Nicholas's deaths—the first Jewish, the second Quaker—were strikingly different. Yet they served common goals: announcing that a death had occurred, ensuring social support, celebrating the life of the deceased, and conveying a philosophy of life after death.

At the funeral home, Solie's body was washed and shrouded, a Jewish ritual signifying return to a state of purity. Then it was placed in a plain wood casket, and the family gathered—just three days after death, decomposition. To underscore the finality of death, Jewish tradition does not permit viewing of the body; it remains in a closed coffin. Traditionally, the coffin is not left alone until nightfall, in honor of the deceased, the coffin is returned a day-and-night vigil, giving earth from which it sprang into the life-giving earth from which it sprang. Solie's funeral was scheduled as soon as relatives could gather—just three days after death. Solie's husband and children symbolized their grief by cutting a black ribbon and pinning it to their clothing. The rabbi recited psalms of comfort, and the family sang. The service continued at the graveside. Once the coffin had been lowered into the ground, the coffin and tombstone were turned facing earth on top of burial. The service concluded with the Kaddish prayer, which affirms life while accepting death.

At home, the family lit a memorial candle, which burned throughout the seven-day mourning period. A meal of consolation, prepared by others, followed, creating a warm sense of community. Jewish custom prescribes that after 30 days, life most gradually returns to normal. When a parent dies, the mourning period is extended to 12 months. Nicholas was cremated promptly. During the next week, relatives and close friends gathered with Grace and Sasha at their home. Together, they planned a memorial service to celebrate Nicholas's life.

When people arrived on the appointed day, a clerk of the Friends (Quaker) Meeting welcomed them and explained to newcomers the Quaker custom of worshipping silently, with those who feel moved to speak rising at any time to share thoughts and feelings. Many mourners offered personal statements about Nicholas or read poems and selections from Scripture. After concluding comments from Grace and Sasha, everyone joined hands to conclude the service. A reception for the family followed.

Quakers give little attention to hope of heaven or fear of hell, focusing mainly on "salvation by character"—working for justice, justice, and a living community.

In recent years, virtual cemeteries have arisen on the Internet, which allow postings whenever bereaved individuals feel ready to tributes at little or no cost, and continuous, easy access to the memorial. Most creators of Web tributes choose to tell personal stories of their loved ones, rather than highlighting a laugh, a favorite joke, or a touching moment. Some speak directly to their loved ones. Goodbooks offer a place for visitors to connect with other mourners who provide a means for people excluded from traditional death rituals to engage in public mourning. The following "graveside" is this highly flexible medium for mourning:

Kalash mourners in rural Pakistan surround the body of a community member, who is carried to his grave in his bed, which are introduced to view of any outsiders the dead may face on their final journey.

I wish I could maintain contact with you, to keep alive the vivid memories of your impact on my life... Because I cannot visit your grave today, I use this means to tell you how much you are loved.

Applying What We Know Tables

In this feature, I summarize research-based applications on many issues, speaking directly to students as parents or future parents and to those pursuing different careers or areas of study, such as teaching, health care, counseling, or social work. The tables include *Supporting Early Language Learning*, *Regulating Screen Media Use*, and *Relieving the Stress of Caring for an Aging Parent*.

**Social Issues: Health** boxes address values and practices relevant to physical and mental health. Examples include *A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies*, *Family Stressors and Childhood Obesity*, and *The Silver Lining in Life's Adversities*.

**Biology and Environment** boxes highlight growing attention to the complex, bidirectional relationship between biology and environment. Examples include *The Tutsi Genocide and Epigenetic Transmission of Maternal Stressors to Children*, *Transgender Children*, and *Experience Corps: Promoting Retired Adults' Physical and Mental Health and Children's Academic Success*.

**Cultural Influences** boxes deepen the attention to culture threaded throughout the text. They highlight both cross-cultural and multicultural variations in human development—for example, *Immigrant Youths: Adapting to a New Land*, *The Flynn Effect: Massive Generational Gains in IQ*, and *Cultural Variations in Mourning Behavior*.

178 CHAPTER 5 Cognitive Development in Infancy and Toddlerhood

Applying what we Know

Supporting Early Language Learning

STRATEGY	CONSEQUENCE
Respond to coos and babbles with speech sounds and words.	Encourages experimentation with sounds that can later be blended into first words.
Establish joint attention and comment on what child sees.	Provides experience with the turn-taking pattern of human conversation.
Play social games, such as pat-a-cake and peekaboo.	Predicts earlier onset of language and faster vocabulary development.
Engage toddlers in joint make-believe play.	Provides experience with the turn-taking pattern of human conversation.
Engage toddlers in frequent conversations.	Promotes all aspects of conversational dialogue.
Read to toddlers often, engaging them in dialogues about picture books.	Provides faster early language development and academic success during the school years.
	Provides exposure to many aspects of language, including vocabulary, grammar, communication skills, and information about written symbols and story structures.

Compared to their higher-SES agemates, children from low-SES homes usually have smaller vocabularies. By 18 to 24 months, they are slower at word comprehension and have acquired 30 percent fewer words (Fernald, Marchand, & Weisleder, 2013). Limited parent-child conversation and book reading are major factors. On average, a middle-SES child is read for 1,000 hours between 1 and 5 years, a low-SES child for only 25 hours (Neuman, 2003).

Not surprisingly, rate of early vocabulary growth is a strong predictor of low-SES children's vocabulary size at kindergarten entry, which forecasts their later literacy skills and academic success (Rowe, Raudenbush, & Goldin-Meadow, 2012). Higher-SES mothers have more opportunities to catch up in early childhood. Young children have distinct styles of early language learning. Caitlin and Grace, like most toddlers, use a **referential style**: their vocabularies consisted mainly of words that refer to objects. A smaller number of toddlers use an **expressive style**: compared to referential children, they produce many more social formulas and pronouns ("thank you," "close," "I want it"). These styles reflect early ideas about the functions of language. Caitlin and Grace, for example, thought words were for naming things. In contrast, expressive-style children believe words are for talking about people's feelings and needs (Bates et al., 1994). The vocabularies of referential-style toddlers grow faster because all languages contain many more object labels than social phrases.

What accounts for a toddler's language style? Rapidly developing referential-style children's language style? Rapidly active interest in exploring objects. They also eagerly imitate their parents' frequent naming of objects (Masur & Rodemsky, 1999). Expressive-style children's language style? Their parents more often use verbal routines ("How are you?" "It's no trouble") that support social relationships (Gallagher, 1987).

The two language styles are also linked to culture. Object words (nouns) are particularly common in the vocabularies of English-speaking toddlers, but Chinese, Japanese, and Korean toddlers have more words for actions (verbs) and social routines. Mothers' speech in each culture reflects this difference (Chan, Branclone, & Tardif, 2009; Chan et al., 2011; Choi & Gopnik, 1995; Fernald & Morikawa, 1993). American mothers frequently label objects when interacting with their babies. Asian mothers, perhaps because of a cultural emphasis on the importance of group membership, emphasize actions and social routines. Also, in Mandarin, sentences often begin with verbs, making action words especially salient to Mandarin-speaking toddlers.

At what point should parents be concerned if their child talks very little or not at all? If a toddler's language development is greatly delayed when compared with the norms in Table 5.3 (page 175), then parents should consult the child's doctor or a speech and language therapist. Late babbling may be a sign of intervention (Rowe, Raudenbush, & Goldin-Meadow, 2012). Some toddlers who do not follow simple directions or who, after age 2, have difficulty putting their thoughts into words may suffer from a hearing impairment or a language disorder that requires immediate treatment.

Supporting Early Language Development

Consistent with the interactionist view, a rich social environment builds on young children's natural readiness to acquire language. For a summary of how caregivers can consciously support language development, see the following text.

## Milestones Tables

A Milestones table appears at the end of each age division of the text. These tables summarize major physical, cognitive, language, emotional, and social attainments, providing a convenient aid for reviewing the chronology of human development.

### Milestones Development in Infancy and Toddlerhood

#### BIRTH–6 MONTHS

**Physical**

- Height and weight increase rapidly. (116)
- Newborn reflexes decline. (101–103)
- Distinguishes basic tastes and odors; prefers sweet-tasting foods. (108)
- Responses can be classically and operantly conditioned. (130–131)
- Habituates to unchanging stimuli; recovers to novel stimuli. (131–132)
- Sleep is increasingly organized into a night-day schedule. (125)
- Holds head up, rolls over, and grasps objects. (134, 136)
- Perceives auditory and visual stimuli as organized patterns. (138, 140, 141–142)
- Shows sensitivity to motion, then binocular, and finally foveal visual acuity; prefers human facial patterns; recognizes features of mother's face. (142)
- Masters a wide range of intermodal (visual, auditory, and tactile) relationships. (144)

**Cognitive**

- Engages in immediate and deferred imitation of adults' facial expressions. (132–133, 154)
- Repeats chance behaviors that lead to pleasurable and interesting results. (151–152)
- Has some awareness of many physical properties (including object permanence) and basic numerical knowledge. (153–154, 158–159)

#### 7–12 MONTHS

**Physical**

- Approaches adultlike sleep-wake schedule. (125)
- Sits alone, crawls, and walks. (134)

**Language**

- Coos and, by end of this period, babbles. (175)
- Begin to establish joint attention with caregiver, who labels objects and events. (176)
- By end of this period, comprehends some word meanings. (176)

**Emotional/Social**

- Social smile and laughter emerge. (185)
- Matches facial tone of caregiver in face-to-face conversations; later, expects matched responses. (188)
- Distinguishes positive from negative emotion in voice and facial expressions. (188)
- Emotional expressions become well-organized and meaningfully related to environmental events. (189)
- Regulates emotion by shifting attention and self-soothing. (189)
- Smiles, laughs, and babbles more to caregiver than to a stranger. (197)
- Awareness of self as physically distinct from surroundings increases. (207)

**Cognitive**

- Engages in intentional, goal-directed behavior. (152)
- Finds object hidden in an initial location. (152)
- Recall memory improves, as indicated by gains in deferred imitation of adults' actions. (154–155, 163)
- Too lost in problem solving emerges; solves simple problems by analogy to a previous problem. (155)
- Categorizes objects on the basis of subtle sets of features, even when the perceptual contrast between categories is minimal. (164)

#### 19–24 MONTHS

**Physical**

- Walks up stairs with help, jumps, and walks on tiptoe. (134)
- Manipulates small objects with good coordination. (137)

**Cognitive**

- Solves simple problems suddenly, through representation. (152)
- Finds a hidden object that has been moved while out of sight. (152)
- Engages in make-believe play, using simple actions experienced in everyday life. (153, 168)

**Language**

- Steadily adds to vocabulary. (175, 177)
- Actively joins in play with familiar adults, practicing the turn-taking pattern of conversation. (176)
- By end of this period, produces 50 words. (175)

**Emotional/Social**

- Realizes that others' emotional reactions may differ from one's own. (188)
- Complies with simple directives. (209)

**Language**

- Engages in deferred imitation of actions an adult tries to produce, even if not fully realized. (155)
- Categorizes objects conceptually, on the basis of common function or behavior. (164–165)
- Begins to use language as a flexible symbolic tool to modify existing mental representations. (154)
- Produces 200 to 250 words. (175)
- Combines two words. (177)

**Emotional/Social**

- Self-conscious emotions (shame, embarrassment, guilt, envy, and pride) emerge. (188–189)
- Acquires a vocabulary for talking about feelings. (189)
- Begins to use language to assist with emotional self-regulation. (189–190)
- Begins to tolerate caregiver's absences more easily; separation anxiety declines. (197)
- Recognizes image of self and, by end of this period, uses own name or personal pronoun to refer to self. (207)
- Shows signs of empathy. (208)
- Categorizes self and others on the basis of age, sex, physical characteristics, and goodness and badness. (208)
- Shows gender-stereotyped preferences. (208)
- Self-control, as indicated by delay of gratification, emerges. (209)

Note: Numbers in parentheses indicate the page or pages on which each milestone is discussed.

208 CHAPTER 6 Emotional and Social Development in Infancy and Toddlerhood

**FIGURE 6.4** Mirror self-recognition at 19 months in four cultures. Urban middle SES German and East Indian toddlers, whose mothers emphasized autonomous child-rearing goals, attained mirror self-recognition earlier than Noo toddlers and toddlers of rural East India, whose mothers emphasized relational child-rearing goals. (Based on Kärtner et al., 2012)

### Categorizing the Self

By the end of the second year, language becomes a powerful tool in self-development. Between 18 and 30 months, children develop a **categorical self** as they classify themselves and others on the basis of age (“baby,” “boy,” or “man”), sex (“boy” or “girl”), physical characteristics (“big,” “strong”), and even goodness versus badness (“I a good girl,” “Tommy mean!”) and competencies (“Did I do it?” “I can!”) (Stokop, Gralinski, & Kopp, 1990). Toddlers use their limited understanding of these social categories to organize their own behavior. As early as 17 months, they select and play in a more involved way with toys that are stereotyped for their own gender—dolls and tea sets for girls, trucks and cars for boys. Their ability to label their own gender predicts a sharp rise in these play preferences over the next few months (Zosuls et al., 2009). Then parents encourage gender-typed behavior by responding more positively when toddlers display it (Hines, 2015). As we will see in Chapter 8, gender typing increases dramatically during early childhood.

### Self-Control

Self-awareness also contributes to effortful control, the extent to which children can inhibit impulses, manage negative emotion, and behave in socially acceptable ways. To behave in a self-controlled fashion, children must think of themselves as separate, autonomous beings who can direct their own actions. And they must have the representational and memory capacities to

This father encourages compliance and the beginnings of self-control. The toddler joins in the task with an eager, willing spirit, which suggests he is adopting the adult's directive as his own.

### Self-Awareness and Early Emotional and Social Development

Self-awareness quickly becomes a central part of children's emotional and social lives. Recall that self-conscious emotions depend on a strengthening sense of self. Self-awareness also leads to first efforts to understand another's perspective. Older toddlers who have experienced sensitive caregiving draw on their advancing capacity to distinguish what happens to oneself from what happens to others to express first signs of **empathy**—the ability to understand another's emotional state and feel with that person, or respond emotionally in a similar way. For example, they communicate concern when others are distressed and may offer what they themselves find comforting—a hug, a reassuring comment, or a favorite doll or blanket (Hoffman, 2000; Moren, Kline, & Robinson, 2008).

Finally, the perspective taking that accompanies toddlers' firmer sense of self enables them to cooperate in resolving disputes over objects and playing games (Caplan et al., 1991). It also leads to clearer awareness of how to upset others. One 18-month-old heard her mother talking to another adult about an older sibling: “Anny is really frightened of spiders” (Dunn, 1989, p. 107). The innocent-looking toddler ran to the bedroom, returned with a toy spider, and pushed it in front of Anny's bed!

## In-Text Key Terms with Definitions, End-of-Chapter Term List, and End-of-Book Glossary

In-text highlighting of key terms and definitions encourages students to review the central vocabulary of the field in greater depth by rereading related information. Key terms also appear in an end-of-chapter page-referenced term list and an end-of-book glossary.

## Enhanced Art and Photo Program

Colorful graphics present concepts and research findings with clarity and attractiveness, thereby aiding student understanding and retention. Each photo has been carefully selected to complement text discussion and to represent the diversity of children, adolescents, and adults around the world.

### CHAPTER 10 Emotional and Social Development in Middle Childhood 363

#### Gender Typing (p. 350)

**10.7 What changes in gender-stereotyped beliefs and gender identity occur during middle childhood?**

- School-age children extend their awareness of gender stereotypes to personality traits and academic skills, and they also broaden their view of what males and females can do.
- Boys strengthen their identification with masculine traits, whereas girls move away from identification with “other gender” activities. Gender identity includes self-evaluations of gender typicality, competitiveness, and the pressure to conform to gender roles—each of which affects adjustment.

**10.8 How do parent-child communication and sibling relationships change to middle childhood?**

- Despite declines in time spent with parents, coregulation allows parents to exercise greater oversight over children, who increasingly make their own decisions.
- Sibling rivalry tends to increase with participation in a wider range of activities and more frequent parental comparisons. Only children rated personality traits and life higher in self-esteem, school performance, and educational attainment.

**10.9 What factors influence children's adjustment to divorce and blended family arrangements?**

- Marital breakup is often quite stressful for children. Individual differences are affected by parental psychological health, financial well-being, child characteristics (age, temperament, and sex), and social supports. Children with difficult temperaments are at greater risk for adjustment problems. Divorce is linked to early relationship difficulties.

The overriding factor in positive adjustment following divorce is effective parenting. Positive father-child relationships are protective, as are teachers, siblings, and friends. However, medication period surrounding divorce. The success of joint custody depends on effective coparenting.

**Family Influences (p. 351)**

**10.10 How do maternal employment and life in dual career families affect school-age children?**

- When employed mothers remain committed to less gender-stereotyped beliefs, better achievement, and lower behavior problems. In dual-career families, the father's willingness to share responsibilities is a crucial factor. Workplace supports help parents in their child-rearing roles.
- In blended, or recombinated, families, stepmothers' families tend to have more adjustment problems. Stepparents who more into their roles gradually help children adjust.

**10.11 How do maternal employment and life in dual career families affect school-age children?**

- When employed mothers remain committed to less gender-stereotyped beliefs, better achievement, and lower behavior problems. In dual-career families, the father's willingness to share responsibilities is a crucial factor. Workplace supports help parents in their child-rearing roles.
- Authoritative child-rearing, parental involvement, and regular after-school chores lead to self-care goals. “After-care” programs also aid school performance and emotional and social adjustment, especially for low-SES children.

#### Some Common Problems of Development (p. 356)

**10.11 Civic concern fears and anxieties in middle childhood**

- School-age children's fears include physical harm, media events, academic failure, parents' loss. Children with inhibited temperaments are at higher risk of developing phobias. Harsh living conditions can also cause severe anxiety.

**10.12 Discuss factors related to child sexual development, and its prevention and treatment.**

- Child sexual abuse is typically committed by those boys. Abusers have characteristics that predispose them toward sexual exploitation of children. Reported cases are strongly associated with often have never adjustment problems.
- Treatment for abused children typically requires crisis, educational programs that teach children to recognize inappropriate sexual advances and identify sources of help reduce the risk of sexual abuse.

**10.13 Cite factors that foster resilience in middle childhood.**

- Only a modest relationship exists between stress, life experiences and psychological disturbance in childhood. Children's personal characteristics, school, community, and social resources predict resilience.

#### Important Terms and Concepts

blended, or recombinated, families (p. 356)	peer acceptance (p. 347)	problems centered coping (p. 342)
comparative children (p. 347)	peer group (p. 346)	prosocial practice (p. 348)
coregulation (p. 352)	peer victimization (p. 346)	rejected-aggressive children (p. 348)
emotional versus identity (p. 346)	person praise (p. 339)	rejected-withdrawn children (p. 348)
inhibited temperament (p. 339)	phobia (p. 358)	self-care children (p. 347)
maternal employment (p. 350)	popular children (p. 347)	self-care children (p. 347)
maternal-oriented attribution (p. 339)	popular prosocial children (p. 348)	social comparisons (p. 348)
neglected children (p. 347)		

## ACKNOWLEDGMENTS

The dedicated contributions of many individuals helped make this book a reality and contributed to refinements and improvements in this seventh edition.

## REVIEWERS

An impressive cast of over 150 reviewers has provided many helpful suggestions and constructive criticisms, as well as encouragement and enthusiasm for the organization and content of the text. I am grateful to each one of them.

### For the Seventh Edition

Cheryl Anagnopoulos, Black Hills State University  
 Donna Baptiste, Northwestern University  
 Carolyn M. Barry, Loyola University Maryland  
 Gina Brelsford, Penn State–Harrisburg

## EDITORIAL AND PRODUCTION TEAM

I cannot begin to express what a great pleasure it has been, once again, to work with Tom Pauken, Managing Editor, who oversaw the preparation of the third, fifth, and sixth editions of *Development Through the Lifespan* and who returned to edit this seventh edition along with its supplements package. Tom's unmatched dedication to my titles, keen organizational skills, responsive day-to-day communication, careful review of manuscript, insightful suggestions, interest in the subject matter, patience, and sense of humor (at just the right moments) greatly enhanced the quality of the text and made it possible for me to keep pace with Pearson's tight revision time frame. I greatly look forward to working with Tom on future projects.

My sincere thanks, as well, to Roth Wilkofsky, Senior Publisher, for crafting a caring climate at Pearson in which to prepare this revision and for bringing the publishing team together in New York for the seventh edition planning meeting. I have benefited greatly from Roth's astute problem solving and encouragement, wide-ranging knowledge and experience, and cordiality.

Donna Simons and Liz Napolitano, Senior Production Managers, coordinated the complex production tasks, transforming my manuscript into an exquisitely beautiful text. I am deeply grateful for their keen aesthetics, attention to detail, flexibility, efficiency, and thoughtfulness.

Rachel Trapp, Assistant Editor, has been nothing short of amazing. In addition to spending countless hours searching, gathering, and organizing scholarly literature, she assisted with a wide array of editorial and production tasks. Judy Ashkenaz and Michelle McSweeney, Development Editors, carefully reviewed and commented on each chapter, helping to ensure that reviewers' comments were diligently considered and that every thought would be clearly expressed and well developed. Lorretta Palagi provided outstanding copyediting and careful compilation of the references list.

The supplements package benefited from the talents and dedication of several individuals. Judy Ashkenaz wrote the new Lecture Enhancements for the Instructor's Resource Manual and revised its chapter summaries and outlines. Kimberly Michaud prepared a superb Test Bank, and Julie Hughes, Denise Wright, and Rachel Trapp carefully crafted the online assessments. Rachael Payne designed and wrote a highly attractive PowerPoint presentation. Maria Henneberry and Phil Vandiver of Contemporary Visuals in Bloomington, Illinois, prepared an inspiring set of new video segments.

A final word of gratitude goes to my family, whose love, patience, and understanding have enabled me to be wife, mother, teacher, researcher, and text author at the same time. My sons, David and Peter, grew up with my texts, passing from childhood

to adolescence and then to adulthood as successive editions were written. David has a special connection with the books' subject matter as an elementary school teacher. Peter is now an experienced attorney, and his vivacious and talented wife Melissa an accomplished linguist and university professor. All three continue to enrich my understanding through reflections on events and progress in their own lives. Finally, I thank my husband, Ken, for willingly making room in our lives for the immensely demanding endeavor of authoring seven editions of *Development Through the Lifespan*.

Laura E. Berk

## mydevelopmentlab

**MyDevelopmentLab** is a collection of online homework, tutorial, and assessment products designed to improve college and university students' learning. Authored by Laura Berk, MyDevelopmentLab for *Development Through the Lifespan*, Seventh Edition, engages students through active learning and promotes in-depth mastery of the subject matter, thereby fostering more thorough preparation for class, quizzes, and exams.

- A **Personalized Study Plan** analyzes students' study needs into three levels: Remember, Understand, and Apply.
- A **Variety of Assessments** enable continuous evaluation of students' learning.
- The **Gradebook** helps students track progress and get immediate feedback. Automatically graded assessments flow into the Gradebook, which can be viewed in MyDevelopmentLab or exported.
- The **eText** allows students to highlight relevant passages and add notes. Access the eText through a laptop, iPad®, or tablet—or download the free app to use on tablets.
- **Extensive video footage** includes NEW segments produced by author Laura Berk.
- **Multimedia simulations** include NEW topics, with simulations designed by author Laura Berk to seamlessly complement the text.
- **Careers in Human Development** explains how studying human development is essential for a wide range of career paths. This tool features more than 25 career overviews, which contain interviews with actual practitioners, educational requirements, typical day-to-day activities, and links to websites for additional information.
- **MyVirtualLife** is a pair of interactive web-based simulations. The first allows students to rear a child from birth to age 18 and monitor the effects of their parenting decisions over time. In the second, students make personal decisions and see the impact of those decisions on their simulated future selves.

For a sampling of MyDevelopmentLab's rich content, visit [www.mydevelopmentlab.com](http://www.mydevelopmentlab.com).

## REVEL™

REVEL is an immersive learning experience designed for the way today's students read, think, and learn. Built in collaboration with educators and students nationwide, REVEL is the newest, fully digital method of delivering course content.

REVEL further enlivens the text, with interactive media and assessments—integrated within the authors' narrative—that provide opportunities for students to deeply engage with course content while reading. Greater student engagement leads to more thorough understanding of concepts and improved performance throughout the course.

To learn more about REVEL, visit [www.pearsonhighered.com/REVEL](http://www.pearsonhighered.com/REVEL).

## INSTRUCTOR RESOURCES

In addition to MyDevelopmentLab, several other author-produced instructor materials accompany *Development Through the Lifespan's* seventh edition. Altogether, these resources enhance student learning and engagement in the course content.

**Instructor's Resource Manual (IRM)** This thoroughly revised IRM can be used by first-time or experienced instructors to enrich classroom experiences. Two new lecture enhancements accompany each chapter, presenting cutting-edge topics, with article citations and suggestions for expanding on chapter content in class.

**Test Bank** The Test Bank contains over 2,000 multiple-choice and essay questions, all of which are page-referenced to the chapter content and also classified by type.

**Pearson MyTest** This secure online environment allows instructors to easily create exams, study guide questions, and quizzes from any computer with an Internet connection.

**PowerPoint Presentation** The PowerPoint presentation provides outlines and illustrations of key topics for each chapter of the text.

**"Explorations in Lifespan Development" DVD and Guide** This revised DVD, designed for classroom use, is over nine hours in length and contains more than 80 four- to ten-minute narrated segments, 20 of which are new to this edition, that illustrate theories, concepts, and milestones of human development. The DVD and Guide are available only to instructors who are confirmed adopters of the text.

# About the Cover Art

© KEN KASHIAN

Growing up in Depression-era Detroit, Harold Gregor displayed passion for and talent in art as a child. As early as kindergarten, he drew—so much so that he recalls being placed in the corner for wasting paper. He earned his bachelor’s degree from Wayne State University, master’s degree from Michigan State University, and Ph.D. from Ohio State University in painting. After a decade of teaching and experimentation with diverse artistic styles in southern California, he moved to the American heartland, joining the faculty at Illinois State University in 1970.

The Illinois farm and prairie landscape quickly became a compelling source of inspiration, and Gregor gained national prominence as one of the foremost American Photo-realist painters. Starting with close-up views of corn cribs, an indigenous form of architecture that fascinated him, he soon moved to panoramas and aerial views of prairie farm scenes, introducing imaginative colors that accentuated the unique and varied beauty of the Midwestern landscape.

In 2004, while climbing a cliff trail in Italy, he fell and broke his right wrist. With his right arm in a cast, he transformed an obstacle into an opportunity: He began to paint with his left hand. Once his right arm healed, he refined his left-handed paintings, eventually arriving at brilliantly colorful, abstract stylistic innovations he calls Vibrascapes, of which the dazzling, energetic image on the cover of this text is an example.

Now a distinguished professor emeritus, Harold Gregor is the epitome of “successful aging.” At age 87, he continues to paint prolifically, prepare new exhibitions, and teach. On his studio wall can be found a Chinese proverb, which reads, “What happiness to wake alive again into this same gray world of winter rain.” He says the proverb reminds him that although growing older is accompanied by unforeseen challenges, he feels blessed each day to do what he enjoys most: painting and teaching.

Harold Gregor’s paintings have been shown at the White House, the American Embassy in Moscow, and the Art Institute of Chicago. They have won numerous prestigious awards and can be viewed in galleries across the United States. To learn more about his life and work, visit [www.hgregor.com](http://www.hgregor.com); and watch the video segment, *Creativity in Late Life*, that accompanies this text.

***Legend for Photos Accompanying Sofie's Story***

Sofie's story is told in Chapters 1 and 19, from her birth to her death. The photos that appear at the beginning of Chapter 1 follow her through her lifespan and include family members of two succeeding generations.

**Page 2**

1. Sofie, age 18, high school graduation.
2. Sofie as a baby, with her mother.
3. Sofie, age 6, with her brother, age 8.
4. Sofie's German passport.
5. Sofie, age 60, and daughter Laura on Laura's wedding day.
6. Sofie and Phil, less than two years before Sofie died.
7. Sofie's grandsons, David and Peter, ages 5 and 2, children of Laura and Ken.
8. Laura, Ken, and sons Peter and David, ages 10 and 13, on the occasion of David's Bar Mitzvah.
9. Peter and Melissa on their wedding day.
10. David, toasting Peter and Melissa's marriage.
11. Laura and Ken, at family gathering.

# chapter 1

## History, Theory, and Research Strategies

This photo essay chronicles the life course and family legacy of Sofie Lentschner. It begins in the early twentieth century with Sofie's infancy and concludes in the early twenty-first century, nearly four decades after Sofie's death, with the wedding of a grandson. For a description of each photo, see the legend on page 1.

### Studying Development

Common Research Methods • General Research Designs • Designs for Studying Development

### ■ CULTURAL INFLUENCES Immigrant Youths: Adapting to a New Land

### Ethics in Lifespan Research

Sofie Lentschner was born in 1908, the second child of Jewish parents who made their home in Leipzig, Germany, a city of thriving commerce and cultural vitality. Her father was a successful businessman and community leader, her mother a socialite well-known for her charm,

beauty, and hospitality. As a baby, Sofie displayed the determination and persistence that would be sustained throughout her life. She sat for long periods inspecting small objects with her eyes and hands. The single event that consistently broke her gaze was the sound of the piano in the parlor. As soon as Sofie could crawl, she steadfastly pulled herself up to finger its keys and marveled at the tinkling sounds.

By the time Sofie entered elementary school, she was an introspective child, often ill at ease at the festive parties that girls of her family's social standing were expected to attend. She immersed herself in schoolwork, especially in mastering foreign languages—a regular part of German elementary and secondary education. Twice a week, she took piano lessons from the finest teacher in Leipzig.

By the time Sofie graduated from high school, she spoke English and French fluently and had become an accomplished pianist. Whereas most German girls of her time married by age 20, Sofie postponed serious courtship in favor of entering university. Her parents began to wonder whether their intense, studious daughter would ever settle into family life.

Sofie wanted marriage as well as education, but her plans were thwarted by the political turbulence of her times. When Hitler rose to power in the early 1930s, Sofie's father, fearing for the safety of his wife and children, moved the family to Belgium. Conditions for Jews in Europe quickly worsened.

The Nazis plundered Sofie's family home and confiscated her father's business. By the end of the 1930s, Sofie had lost contact with all but a handful of her aunts, uncles, cousins, and childhood friends, many of whom (she later learned) were herded into cattle cars and transported to Nazi death camps. In 1939, as anti-Jewish laws and atrocities intensified, Sofie's family fled to the United States.

As Sofie turned 30, her parents, convinced that she would never marry and would need a career for financial security, agreed to support her return to school. Sofie earned two master's degrees, one in music and the other in librarianship. Then, on a blind date, she met Philip, a U.S. army officer. Philip's calm, gentle nature complemented Sofie's intensity and worldliness. Within six months they married. During the next four years, two daughters and a son were born.

When World War II ended, Philip left the army and opened a small men's clothing store. Sofie divided her time between caring for the children and helping Philip in the store. Now in her forties, she was a devoted mother, but few women her age were still rearing young children. As Philip struggled with the business, he spent longer hours at work, and Sofie often felt lonely. She rarely touched the piano, which brought back painful memories of youthful life plans shattered by war. Sofie's sense of isolation

COURTESY OF LAURA E. BERK

and lack of fulfillment frequently left her short-tempered. Late at night, she and Philip could be heard arguing.

As Sofie's children grew older, she returned to school again, this time earning a teaching credential. Finally, at age 50, she launched a career, teaching German and French to high school students and English to newly arrived immigrants. Besides easing her family's financial difficulties, she felt a gratifying sense of accomplishment and creativity. These years were among the most energetic and satisfying of Sofie's life. She had an unending enthusiasm for teaching—for transmitting her facility with language, her firsthand knowledge of the consequences of hatred and oppression, and her practical understanding of how to adapt to life in a new land. She watched her children, whose young lives were free of the trauma of war, adopt many of her values and commitments and begin their marital and vocational lives at the expected time.

Sofie approached age 60 with an optimistic outlook. Released from the financial burden of paying for their children's college education, she and Philip looked forward to greater leisure. Their affection and respect for each other deepened. Once again, Sofie began to play the piano. But this period of contentment was short-lived.

One morning, Sofie awoke and felt a hard lump under her arm. Several days later, her doctor diagnosed cancer. Sofie's spirited disposition and capacity to adapt to radical life changes helped her meet the illness head on. She defined it as an enemy to be fought and overcome. As a result, she lived five more years. Despite the exhaustion of chemotherapy, Sofie maintained a full schedule of teaching duties and continued to visit and run errands for her aging mother. But as she weakened physically, she no longer had the stamina to meet her classes. Bedridden for the last few weeks, she slipped quietly into death with Philip at her side. The funeral chapel overflowed with hundreds of Sofie's students.

One of Sofie's three children, Laura, is the author of this book. Married a year before Sofie died, Laura and her husband, Ken, often think of Sofie's message, spoken privately on the eve of their wedding day: "I learned from my own life and marriage that you must build a life together but also a life apart. You must

grant each other the time, space, and support to forge your own identities, your own ways of expressing yourselves and giving to others. The most important ingredient of your relationship must be respect."

COURTESY OF LAURA E. BERK

Laura and Ken settled in a small Midwestern city, near Illinois State University, where they served on the faculty for many years—Laura in the Department of Psychology, Ken in the Department of Mathematics. They have two sons, David and Peter, to whom Laura has related many stories about Sofie's life and who carry her legacy forward. David shares his grandmother's penchant for teaching; he is a third-grade teacher. Peter, a lawyer, shares her love of music, and his wife Melissa—much like Sofie—is both a talented linguist and a musician. When Peter asked Melissa to marry him, he placed a family heirloom on her finger—an engagement ring that had belonged to Sofie's aunt, who perished in a Nazi death camp. In the box that held

the ring, Melissa found a written copy of the story of Sofie and her family.

Sofie also had a lifelong impact on many of her students. A professor of human development wrote to Laura:

I teach a class in lifespan development. When I opened the textbook and saw the pictures of your mother, I was very surprised. I took high school German classes from her. I remember her as a very tough teacher who both held her students accountable and cared about each and every one of us. That she was an incredible teacher did not really sink in until I went to Germany during my [college] years and was able to both understand German and speak it.

Sofie's story raises a wealth of fascinating issues about human life histories:

- What determines the features that Sofie shares with others and those that make her unique—in physical characteristics, mental capacities, interests, and behaviors?
- What led Sofie to retain the same persistent, determined disposition throughout her life but to change in other essential ways?

- How do historical and cultural conditions—for Sofie, the persecution that destroyed her childhood home, caused the death of family members and friends, and led her family to flee to the United States—affect well-being throughout life?
- How does the timing of events—for example, Sofie’s early exposure to multiple languages and her delayed entry into marriage, parenthood, and career—affect development?
- What factors—both genetic and environmental—led Sofie to die sooner than expected?

These are central questions addressed by **developmental science**, a field of study devoted to understanding constancy and change throughout the lifespan (Lerner et al., 2014; Overton & Molenaar, 2015). Great diversity characterizes the interests and concerns of investigators who study development. But all share a single goal: to identify those factors that influence consistencies and transformations in people from conception to death. ●

## A Scientific, Applied, and Interdisciplinary Field

**1.1** What is developmental science, and what factors stimulated expansion of the field?

The questions just listed are not just of scientific interest. Each has *applied*, or practical, importance as well. In fact, scientific curiosity is just one factor that led the study of development to become the exciting field it is today. Research about development has also been stimulated by social pressures to improve people’s lives. For example, the beginning of public education in the early twentieth century led to a demand for knowledge about what and how to teach children of different ages. The interest of the medical profession in improving people’s health required an understanding of physical development, nutrition, and disease. The social service profession’s desire to treat emotional problems and to help people adjust to major life events, such as divorce, job loss, war, natural disasters, or the death of loved ones, required information about personality and social development. And parents have continually sought expert advice about child-rearing practices and experiences that would promote their children’s well-being.

Our large storehouse of information about development is *interdisciplinary*. It has grown through the combined efforts of people from many fields of study. Because of the need for solutions to everyday problems at all ages, researchers from psychology, sociology, anthropology, biology, and neuroscience have joined forces in research with professionals from education, family studies, medicine, public health, and social service, to name just a few. Together, they have created the field as it exists today—a body of knowledge that is not only scientifically important but also relevant and useful.

## Basic Issues

**1.2** Identify three basic issues on which theories of human development take a stand.

Developmental science is a relatively recent endeavor. Studies of children did not begin until the late nineteenth and early twentieth centuries. Investigations into adult development, aging, and change over the life course emerged only in the 1960s and 1970s (Elder & Shanahan, 2006). But speculations about how people grow and change have existed for centuries. As they combined with research, they inspired the construction of *theories* of development. A **theory** is an orderly, integrated set of statements that describes, explains, and predicts behavior. For example, a good theory of infant–caregiver attachment would (1) *describe* the behaviors of babies of 6 to 8 months of age as they seek the affection and comfort of a familiar adult, (2) *explain* how and why infants develop this strong desire to bond with a caregiver, and (3) *predict* the consequences of this emotional bond for future relationships.

Theories are vital tools for two reasons. First, they provide organizing frameworks for our observations of people. In other words, they *guide and give meaning* to what we see. Second, theories that are verified by research provide a sound basis for practical action. Once a theory helps us *understand* development, we are in a much better position *to know how to improve* the welfare and treatment of children and adults.

As we will see, theories are influenced by the cultural values and belief systems of their times. But theories differ in one important way from mere opinion or belief: A theory’s continued existence depends on *scientific verification*. Every theory must be tested using a fair set of research procedures agreed on by the scientific community, and the findings must endure, or be replicated over time.

Within the field of developmental science, many theories offer very different ideas about what people are like and how they change. The study of development provides no ultimate truth because investigators do not always agree on the meaning of what they see. Also, humans are complex beings; they change physically, mentally, emotionally, and socially. No single theory has explained all these aspects. But the existence of many theories helps advance knowledge as researchers continually try to support, contradict, and integrate these different points of view.

This chapter introduces you to major theories of human development and research strategies used to test them. In later chapters, we will discuss each theory in greater depth and also introduce other important but less grand theories. Although there are many theories, we can easily organize them by looking at the stand they take on three basic issues: (1) Is the course of development continuous or discontinuous? (2) Does one course of development characterize all people, or are there many possible courses? (3) What are the roles of genetic and environmental factors—nature and nurture—in development? Let’s look closely at each of these issues.

## Continuous or Discontinuous Development?

How can we best describe the differences in capacities among infants, children, adolescents, and adults? As Figure 1.1 illustrates, major theories recognize two possibilities.

One view holds that infants and preschoolers respond to the world in much the same way as adults do. The difference between the immature and mature being is simply one of *amount or complexity*. For example, when Sofie was a baby, her perception of a piano melody, memory for past events, and ability to categorize objects may have been much like our own. Perhaps her only limitation was that she could not perform these skills with as much information and precision as we can. If this is so, then changes in her thinking must be **continuous**—a process of gradually augmenting the same types of skills that were there to begin with.

According to a second view, infants and children have *unique ways of thinking, feeling, and behaving*, ones quite different from those of adults. If so, then development is **discontinuous**—a process in which new ways of understanding and responding to the world emerge at specific times. From this perspective, Sofie could not yet perceive, remember, and categorize experiences as a mature person can. Rather, she moved through a series of developmental steps, each with unique features, until she reached the highest level of functioning.

Theories that accept the discontinuous perspective regard development as taking place in **stages**—*qualitative* changes in thinking, feeling, and behaving that characterize specific periods of development. In stage theories, development is like climbing a staircase, with each step corresponding to a more mature, reorganized way of functioning. The stage concept also assumes that people undergo periods of rapid transformation as they step up from one stage to the next. In other words, change is fairly sudden rather than gradual and ongoing.

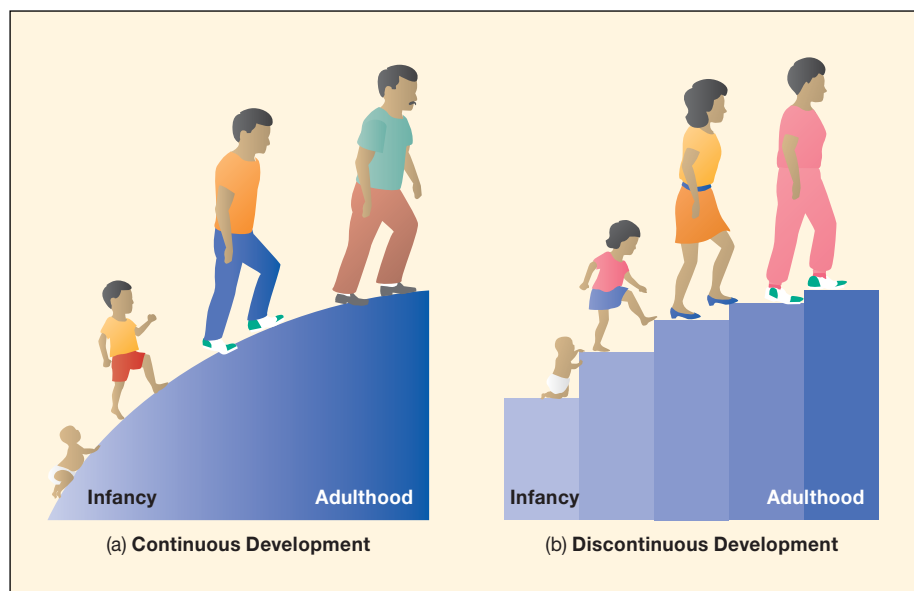

Does development actually occur in a neat, orderly sequence of stages? This ambitious assumption has faced significant challenges. Later in this chapter, we will review some influential stage theories.

## One Course of Development or Many?

Stage theorists assume that people everywhere follow the same sequence of development. Yet the field of human development is becoming increasingly aware that children and adults live in distinct **contexts**—unique combinations of personal and environmental circumstances that can result in different paths of change. For example, a shy individual who fears social encounters develops in very different contexts from those of an outgoing agemate who readily seeks out other people. Children and adults in non-Western village societies have experiences in their families and communities that differ sharply from those of people in large Western cities. These different circumstances foster different intellectual capacities, social skills, and feelings about the self and others (Kagan, 2013a; Mistry & Dutta, 2015).

As you will see, contemporary theorists regard the contexts that shape development as many-layered and complex. On the personal side, they include heredity and biological makeup. On the environmental side, they include both immediate settings—home, school, and neighborhood—and circumstances more remote from people's everyday lives: community resources, societal values, and historical time period. Furthermore, new evidence is increasingly emphasizing *mutually influential relations* between individuals and their contexts: People not only are affected by but also contribute to the contexts in which they develop (Elder, Shanahan, & Jennings, 2015). Finally, researchers today are more conscious than ever before of cultural diversity in development.

**FIGURE 1.1** Is development continuous or discontinuous? (a) Some theorists believe that development is a smooth, continuous process. Individuals gradually add more of the same types of skills. (b) Other theorists think that development takes place in discontinuous stages. People change rapidly as they step up to a new level and then change very little for a while. With each new step, the person interprets and responds to the world in a reorganized, qualitatively different way. As we will see later, still other theorists believe that development is characterized by both continuous and discontinuous change.

## Relative Influence of Nature and Nurture?

In addition to describing the course of human development, each theory takes a stand on a major question about its underlying causes: Are genetic or environmental factors more important? This is the age-old **nature–nurture controversy**. By *nature*, we mean the hereditary information we receive from our parents at the moment of conception. By *nurture*, we mean the complex forces of the physical and social world that influence our biological makeup and psychological experiences before and after birth.

Although all theories grant roles to both nature and nurture, they vary in emphasis. Consider the following questions: Is the developing person's ability to think in more complex ways largely the result of a built-in timetable of growth, or is it primarily influenced by stimulation from parents and teachers? Do children acquire language rapidly because they are genetically predisposed to do so or because parents teach them from an early age? And what accounts for the vast individual differences among people—in height, weight, physical coordination, intelligence, personality, and social skills? Is nature or nurture more responsible?

A theory's position on the roles of nature and nurture affects how it explains individual differences. Theorists who emphasize *stability*—that individuals who are high or low in a characteristic (such as verbal ability, anxiety, or sociability) will remain so at later ages—typically stress the importance of *heredity*. If they regard environment as important, they usually point to *early experiences* as establishing a lifelong pattern of behavior. Powerful negative events in the first few years, they argue, cannot be fully overcome by later, more positive ones (Bowlby, 1980; Sroufe, Coffino, & Carlson, 2010). Other theorists, taking a more optimistic view, see development as having substantial **plasticity** throughout life—as open to change in response to influential experiences (Baltes, Lindenberger, & Staudinger, 2006; Overton & Molenaar, 2015).

Throughout this book, you will see that investigators disagree, often sharply, on the question of *stability versus plasticity*. Their answers often vary across *domains*, or aspects, of development. Think back to Sofie's story, and you will see that her linguistic ability and persistent approach to challenges were stable over the lifespan. In contrast, her psychological well-being and life satisfaction fluctuated considerably.

### The Lifespan Perspective: A Balanced Point of View

#### 1.3 Describe the lifespan perspective on development.

So far, we have discussed basic issues of human development in terms of extremes—solutions favoring one side or the other. But as we trace the unfolding of the field, you will see that the positions of many theorists have softened. Today, some theorists believe that both continuous and discontinuous changes occur.

© AURORA PHOTOS/ROBERT HARDING

Since the 1960s, researchers have moved from focusing only on child development to investigating development over the entire life course. This woman and her companions on a river rafting trip illustrate the health, vitality, and life satisfaction of many contemporary older adults.

Many acknowledge that development has both universal features and features unique to each individual and his or her contexts. And a growing number regard heredity and environment as inseparably interwoven, each affecting the potential of the other to modify the child's traits and capacities (Lerner et al., 2014; Overton & Molenaar, 2015).

These balanced visions owe much to the expansion of research from a nearly exclusive focus on the first two decades of life to include development during adulthood. In the first half of the twentieth century, it was widely assumed that development stopped at adolescence. Infancy and childhood were viewed as periods of rapid transformation, adulthood as a plateau, and aging as a period of decline. The changing character of the North American population awakened researchers to the idea that gains in functioning are lifelong.

Because of improvements in nutrition, sanitation, and medical knowledge, *average life expectancy* (the number of years an individual born in a particular year can expect to live) gained more in the twentieth century than in the preceding 5,000 years. In 1900, U.S. life expectancy was just under age 50; in 2000, it was 76.8. Today, it is 78.8 years in the United States and even higher in most other industrialized nations, including neighboring Canada. Life expectancy continues to increase; in the United States, it is predicted to reach 84 years in 2050. Consequently, there are more older adults—a worldwide trend that is especially striking in developed countries. People age 65 and older accounted for about 4 percent of the U.S. population in 1900, 7 percent in 1950, and 14 percent in 2013 (U.S. Census Bureau, 2015d).

Older adults are not only more numerous but also healthier and more active. Challenging the earlier stereotype of the withering person, they have contributed to a profound shift in our view of human change. Increasingly, researchers are envisioning it from a *developmental systems perspective*—as a perpetually ongoing process, extending from conception to death, that is molded by a complex network of biological, psychological, and social influences (Lerner, 2015). A leading systems approach is the **lifespan perspective**. Four assumptions make up this broader

view: that development is (1) lifelong, (2) multidimensional and multidirectional, (3) highly plastic, and (4) affected by multiple, interacting forces (Baltes, Lindenberger, & Staudinger, 2006; Smith & Baltes, 1999; Staudinger & Lindenberger, 2003).

## Development Is Lifelong

According to the lifespan perspective, no age period is supreme in its impact on the life course. Rather, events occurring during each major period, summarized in Table 1.1, can have equally powerful effects on future change. Within each period, change occurs in three broad domains: *physical*, *cognitive*, and *emotional/social*, which we separate for convenience of discussion (see Figure 1.2 for a description of each). Yet these domains are not really distinct; they overlap and interact.

Every age period has its own agenda, its unique demands and opportunities that yield certain similarities in development across many individuals. Nevertheless, throughout life, the challenges people face and the adjustments they make are highly diverse in timing and pattern, as the remaining assumptions make clear.

## Development Is Multidimensional and Multidirectional

Think back to Sofie's life and how she continually faced new demands and opportunities. From a lifespan perspective, the challenges and adjustments of development are *multidimensional*—affected by an intricate blend of biological, psychological, and social forces.

Lifespan development is also *multidirectional*, in at least two ways. First, development is not limited to improved performance. Rather, at every period, it is a joint expression of growth and decline. When Sofie directed her energies toward mastering languages and music as a school-age child, she gave up refining other skills to their full potential. Later, when she chose to become a teacher, she let go of other career options. Although gains are especially evident early in life, and losses during the final years, people of all ages can improve current skills and develop new ones, including skills that compensate for reduced functioning (de Frias, 2014; Stine-Morrow et al., 2014). Most older adults, for example, devise compensatory techniques for dealing with their increasing memory failures. They may rely more on external aids, such as calendars and lists, or generate new internal strategies, such as visualizing exactly where they will be and what they will be doing when they must keep an appointment or take medication.

Second, besides being multidirectional over time, change is multidirectional within each domain of development. Although some qualities of Sofie's cognitive functioning (such as memory) probably declined in her mature years, her knowledge of both English and French undoubtedly grew throughout her life. And she also developed new forms of thinking. For example, Sofie's wealth of experience and ability to cope with diverse problems led her to become expert in practical matters—a quality of reasoning called *wisdom*. Recall Sofie's wise advice to Laura and Ken on the eve of their wedding day. We will consider the development of wisdom in Chapter 17. Notice in the examples just mentioned how the lifespan perspective includes both continuous and discontinuous change.

**TABLE 1.1**  
Major Periods of Human Development

PERIOD	APPROXIMATE AGE RANGE	BRIEF DESCRIPTION
Prenatal	Conception to birth	The one-celled organism transforms into a human baby with remarkable capacities to adjust to life in the surrounding world.
Infancy and toddlerhood	Birth–2 years	Dramatic changes in the body and brain support the emergence of a wide array of motor, perceptual, and intellectual capacities and first intimate ties to others.
Early childhood	2–6 years	During the “play years,” motor skills are refined, thought and language expand at an astounding pace, a sense of morality is evident, and children establish ties with peers.
Middle childhood	6–11 years	The school years are marked by improved athletic abilities; more logical thought processes; mastery of fundamental reading, writing, math, and other academic knowledge and skills; advances in self-understanding, morality, and friendship; and the beginnings of peer-group membership.
Adolescence	11–18 years	Puberty leads to an adult-sized body and sexual maturity. Thought becomes abstract and idealistic and school achievement more serious. Adolescents begin to establish autonomy from the family and to define personal values and goals.
Early adulthood	18–40 years	Most young people leave home, complete their education, and begin full-time work. Major concerns are developing a career, forming an intimate partnership, and marrying, rearing children, or pursuing other lifestyles.
Middle adulthood	40–65 years	Many people are at the height of their careers and attain leadership positions. They must also help their children begin independent lives and their parents adapt to aging. They become more aware of their own mortality.
Late adulthood	65 years–death	People adjust to retirement, to decreased physical strength and health, and often to the death of an intimate partner. They reflect on the meaning of their lives.

**FIGURE 1.2 Major domains of development.** The three domains are not really distinct. Rather, they overlap and interact.

## Development Is Plastic

Lifespan researchers emphasize that development is plastic at all ages. Consider Sofie’s social reserve in childhood and her decision to study rather than marry as a young adult. As new opportunities arose, Sofie moved easily into marriage and childbearing in her thirties. And although parenthood and financial difficulties posed challenges, Sofie and Philip’s relationship gradually became richer and more fulfilling. In Chapter 17, we will see that intellectual performance also remains flexible with advancing age. Older adults respond to special training with substantial (but not unlimited) gains in a wide variety of mental abilities (Bamidis et al., 2014; Willis & Belleville, 2016).

Evidence on plasticity reveals that aging is not an eventual “shipwreck,” as has often been assumed. Instead, the metaphor of a “butterfly”—of metamorphosis and continued potential—provides a far more accurate picture of lifespan change. Still, development gradually becomes less plastic, as both capacity and opportunity for change are reduced. And plasticity varies greatly across individuals. Some children and adults experience more diverse life circumstances. Also, as the Biology and Environment box on pages 10–11 indicates, some adapt more easily than others to changing conditions.

## Development Is Influenced by Multiple, Interacting Forces

According to the lifespan perspective, pathways of change are highly diverse because *development is influenced by multiple*

*forces*: biological, historical, social, and cultural. Although these wide-ranging influences can be organized into three categories, they work together, combining in unique ways to fashion each life course.

**Age-Graded Influences.** Events that are strongly related to age and therefore fairly predictable in when they occur and how long they last are called **age-graded influences**. For example, most individuals walk shortly after their first birthday, acquire their native language during the preschool years, reach puberty around age 12 to 14, and (for women) experience menopause in their late forties or early fifties. These milestones are influenced by biology, but social customs—such as starting school around age 6, getting a driver’s license at age 16, and entering college around age 18—can create age-graded influences as well. Age-graded influences are especially prevalent in childhood and adolescence, when biological changes are rapid and cultures impose many age-related experiences to ensure that young people acquire the skills they need to participate in their society.

**History-Graded Influences.** Development is also profoundly affected by forces unique to a particular historical era. Examples include epidemics, wars, and periods of economic prosperity or depression; technological advances like the introduction of television, computers, the Internet, smartphones, and tablets; and changes in cultural values, such as attitudes toward women, ethnic minorities, and older adults. These **history-graded influences** explain why people born around the same

## Biology and Environment

### Resilience

John and his best friend, Gary, grew up in a rundown, crime-ridden, inner-city neighborhood. By age 10, each had experienced years of family conflict followed by parental divorce. Reared from then on in mother-headed households, John and Gary rarely saw their fathers. Both dropped out of high school and were in and out of trouble with the police.

Then their paths diverged. By age 30, John had fathered two children with women he never married, had spent time in prison, was unemployed, and drank alcohol heavily. In contrast, Gary had returned to finish high school, had studied auto mechanics at a community college, and had become manager of a gas station and repair shop. Married with two children, he had saved his earnings and bought a home. He was happy, healthy, and well-adapted to life.

A wealth of evidence shows that environmental risks—poverty, negative family interactions and parental divorce, job loss, mental illness, and drug abuse—predispose children to future problems (Masten, 2013). Why did Gary “beat the odds” and bounce back from adversity?

Research on **resilience**—the ability to adapt effectively in the face of threats to development—is receiving increased attention as investigators look for ways to protect young people from the damaging effects of stressful life conditions. This interest has been inspired by several long-term studies on the relationship of life stressors in childhood to competence and adjustment in adolescence and adulthood (Werner, 2013). In each study, some individuals were shielded from negative outcomes, whereas others had lasting problems. Four broad factors seemed to offer protection from the damaging effects of stressful life events.

#### Personal Characteristics

A child’s genetically influenced characteristics can reduce exposure to risk or lead to experiences that compensate for early stressful events. High intelligence and socially valued talents (in music or athletics, for example) increase the chances that a child will have rewarding experiences in school and in the community that offset the impact of a stressful home life. Temperament is particularly

powerful. Children who have easygoing, sociable dispositions and who can readily inhibit negative emotions and impulses tend to have an optimistic outlook on life and a special capacity to adapt to change—qualities that elicit positive responses from others. In contrast, emotionally reactive and irritable

time—called a *cohort*—tend to be alike in ways that set them apart from people born at other times.

Consider the *baby boomers*, a term used to describe people born between 1946 and 1964, the post–World War II period during which birth rates soared in most Western nations. This population increase was especially sharp in the United States: By 1960, the prewar birth rate had nearly doubled, yielding the largest gain in the nation’s history. The sheer size of the baby-boom generation made it a powerful social force from the time its members became young adults; today, the baby boomers are redefining our view of middle and late adulthood (see the Cultural Influences box above).

#### LOOK and LISTEN

Identify a history-graded influence in your life, and speculate about its impact on people your age. Then ask someone a generation or two older than you to identify a history-graded influence in his or her life and to reflect on its impact.

**Nonnormative Influences.** Age-graded and history-graded influences are normative—meaning typical, or average—because each affects large numbers of people in a similar way. **Nonnormative influences** are events that are irregular: They happen to just one person or a few people and do not follow a predictable timetable. Consequently, they enhance the multidirectionality of development. Nonnormative influences that had a major impact on the direction of Sofie’s life included piano lessons in childhood with an inspiring teacher; delayed marriage, parenthood, and career entry; and a battle with cancer. Because they occur irregularly, nonnormative events are difficult for researchers to capture and study. Yet, as each of us can attest from our own experiences, they can affect us in powerful ways.

Nonnormative influences have become more powerful and age-graded influences less so in contemporary adult development. Compared with Sofie’s era, much greater diversity exists today in the ages at which people finish their education, enter careers, marry, have children, and retire. Indeed, Sofie’s “off-time” accomplishments would have been less unusual had she been

children often tax the patience of people around them (Wang & Deater-Deckard, 2013). For example, both John and Gary moved several times during their childhoods. Each time, John became anxious and angry. Gary looked forward to making new friends and exploring a new neighborhood.

### A Warm Parental Relationship

A close relationship with at least one parent who provides warmth, appropriately high expectations, monitoring of the child's activities, and an organized home environment fosters resilience (Shonkoff & Garner, 2012; Taylor, 2010). But this factor (as well as the next one) is not independent of children's personal characteristics. Children who are self-controlled, socially responsive, and able to deal with change are easier to rear and more likely to enjoy positive relationships with parents and other people. At the same time, children develop more attractive dispositions as a result of parental warmth and attention (Luthar, Crossman, & Small, 2015).

### Social Support Outside the Immediate Family

The most consistent asset of resilient children is a strong bond with a competent, caring

adult. For children who do not have a close bond with either parent, a grandparent, aunt, uncle, or teacher who forms a special relationship with the child can promote resilience (Masten, 2013). Gary received support in adolescence from his grandfather, who listened to Gary's concerns and helped him solve problems. In addition, Gary's grandfather had a stable marriage and work life and handled stressors skillfully. Consequently, he served as a model of effective coping.

Associations with rule-abiding peers who value academic achievement are also linked to resilience (Furman & Rose, 2015). But children who have positive relationships with adults are far more likely to establish these supportive peer ties.

### Community Resources and Opportunities

Community supports—supervision offered by neighborhood adults, high-quality child-care centers and public schools, convenient and affordable health care and social services, libraries, and recreation centers—foster both parents' and children's well-being. In addition, opportunities to participate in community life help older children and adolescents overcome adversity. Extracurricular activities at school,

religious youth groups, scouting, and other organizations teach important social skills, such as cooperation, leadership, and contributing to others' welfare. As participants acquire these competencies, they gain in self-reliance, self-esteem, and community commitment (Leventhal, Dupéré, & Shuey, 2015). As a college student, Gary volunteered for Habitat for Humanity, joining a team building affordable housing in low-income neighborhoods. Community involvement offered Gary opportunities to form meaningful relationships, which further strengthened his resilience.

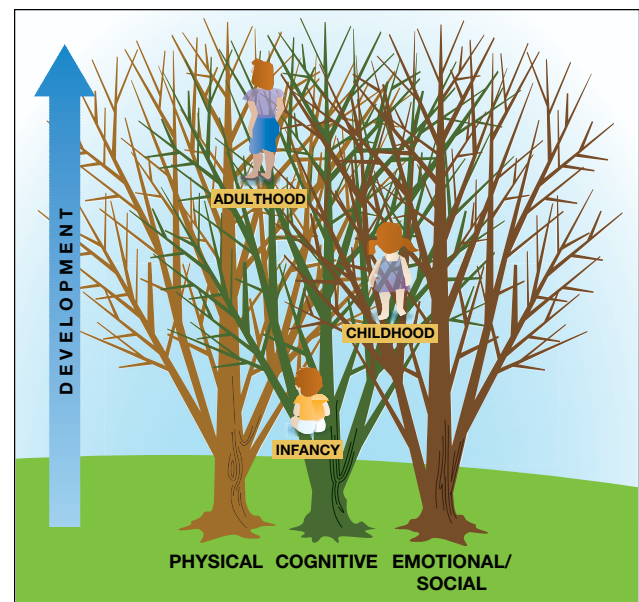

Research on resilience highlights the complex connections between heredity and environment. Armed with positive characteristics, which stem from native endowment, favorable rearing experiences, or both, children and adolescents can act to reduce stressful situations.

But when many risks pile up, they are increasingly difficult to overcome (Obradović et al., 2009). To inoculate children against the negative effects of risk, interventions must not only reduce risks but also enhance children's protective relationships at home, in school, and in the community. This means attending to both the person and the environment—strengthening the individual's capacities while also reducing hazardous experiences.

born two generations later. Age remains a powerful organizer of everyday experiences, and age-related expectations have certainly not disappeared. But age markers have blurred, and they vary across ethnic groups and cultures. The increasing role of nonnormative events in the life course adds to the fluid nature of lifespan development.

Notice that instead of a single line of development, the lifespan perspective emphasizes many potential pathways and outcomes—an image more like tree branches extending in diverse directions, which may undergo both continuous and stagewise transformations (see Figure 1.3). Now let's turn to scientific

**FIGURE 1.3 The lifespan view of development.** Rather than envisioning a single line of stagewise or continuous change (see Figure 1.1 on page 6), lifespan theorists conceive of development as more like tree branches extending in diverse directions. Many pathways are possible, depending on the contexts that influence the individual's life course. Each branch in this treelike image represents a possible skill within one of the major domains of development. The crossing of the branches signifies that the domains—physical, cognitive, emotional, and social—are interrelated.

## Cultural Influences

### The Baby Boomers Reshape the Life Course

From 1946 to 1964, 92 percent of all American women of childbearing age gave birth, averaging almost four children each—a new baby every 8 seconds (Croker, 2007). This splurge of births, which extended for nearly two decades, yielded a unique generation often credited with changing the world. Today, the baby boomers number 74 million adults—about 23 percent of the U.S. population (Colby & Ortman, 2014). Most are middle aged, with the oldest having entered late adulthood.

Several interrelated factors sparked the post–World War II baby boom. Many people who had postponed marriage and parenthood throughout the Great Depression of the 1930s started families in the 1940s, once the economy had improved. With the end of World War II, returning GIs also began to have children. As these two cohorts focused on childbearing, they gave birth to babies who otherwise would have been spaced out over 10 to 15 years. And as economic prosperity accelerated in the 1950s, making larger families affordable, more people married at younger ages and had

several children closely spaced, which led the baby boom to persist into the 1960s (Stewart & Malley, 2004). Finally, after a war, the desire to make babies generally strengthens. Besides replacing massive population loss, new births signify hope that human life will endure.

Compared with their counterparts in the previous generation, many more young baby boomers were economically privileged. They were also the recipients of deep emotional investment from their parents, who—having undergone the deprivations of depression and war—often ranked children as the most enduring benefit of their adult lives. These factors may have engendered optimism, confidence, even a sense of entitlement (Elder, Nguyen, & Caspi, 1985). At the same time, their huge numbers—evident in overflowing school classrooms—may have sparked an intense struggle for individual recognition. By the time the boomers reached early adulthood, this set of traits led critics to label them a narcissistic, indulged, “me” generation.

From the mid-1960s to the early 1970s, the “leading-edge” baby boomers (born in the late

1940s and early 1950s) entered colleges and universities in record numbers, in part because of draft deferments offered to students during the Vietnam War. The boomers became better educated than any previous generation. This cohort—self-focused, socially aware, and in search of distinction—broke

foundations of the field as a prelude to major theories that address various aspects of change.

### Ask yourself

**CONNECT** Distinguish age-graded, history-graded, and nonnormative influences on lifespan development. Cite an example of each in Sofie’s story.

**APPLY** Anna, a high school counselor, devised a program that integrates classroom learning with vocational training to help adolescents at risk for school dropout stay in school and transition to work life. What is Anna’s position on *stability versus plasticity* in development? Explain.

**REFLECT** Describe an aspect of your development that differs from a parent’s or a grandparent’s when he or she was your age. Using influences highlighted by the lifespan perspective, explain this difference in development.

## Scientific Beginnings

**1.4** Describe major early influences on the scientific study of development.

Scientific study of human development dates back to the late nineteenth and early twentieth centuries. Early observations of human change were soon followed by improved methods and theories. Each advance contributed to the firm foundation on which the field rests today.

### Darwin: Forefather of Scientific Child Study

British naturalist Charles Darwin (1809–1882) observed the infinite variation among plant and animal species. He also saw that within a species, no two individuals are exactly alike. From these observations, he constructed his famous *theory of evolution*.

away from their parents' family- and marriage-centered lifestyles. Starting in the mid-sixties, marriage rates declined, age of first marriage rose, and divorce rates increased. And the baby boomers responded to the turbulence of those times—the assassination of President Kennedy in 1963, the Vietnam War, and growing racial tensions—by mobilizing around the antiwar, civil rights, and women's movements, yielding a generation of student activists.

By the time the “trailing-edge” boomers (born in the late 1950s and early 1960s) came of age, these movements had left an enduring mark. Even as they turned toward family life and career development, the boomers continued to search for personal meaning, self-expression, and social responsibility. By midlife, the generation had produced an unusually large number of socially concerned writers, teachers, filmmakers, and labor and community organizers, as well as innovative musicians and artists (Cole & Stewart, 1996). And a multitude of ordinary citizens worked to advance social causes.

As baby-boom women entered the labor market and struggled for career advancement and equal pay, their self-confidence grew, and they paved the way for the next generation:

On average, younger women attained this same level of self-confidence at a much earlier age (Twenge, 2001). And as baby-boom activists pressed for gender and racial equality, they influenced national policy. The 1960s saw laws passed that banned discrimination in employment practices, in racial access to public accommodations, and in sale or rental of housing. By the 1970s, progress in civil rights served as the springboard for the gay and lesbian rights movement.

The baby boomers are healthier, better educated, and financially better off than any previous mid- or late-life cohort (New Strategist Editors, 2015). Their sense of self-empowerment and innovativeness has energized efforts to increase the personal meaningfulness of their worklives and to deepen their lifelong engagement with social causes. Yet another concern of baby-boom midlifers is an intense desire to control the physical changes of aging (Hooymann, Kawamoto, & Kiyak, 2015). Far more than their predecessors, they resist growing old, as indicated by their interest in a wide array of anti-aging products and procedures—from cosmetics to Botox to plastic surgery—that are now a multi-billion-dollar U.S. industry.

Nevertheless, it is important to note that the baby boomers—though advantaged as a generation—are diverse in health status and sense of control over their lives. Those higher in education and income are considerably better off. And because retirement savings were heavily hit by the economic recession of 2007 to 2009, and pension plans with guaranteed fixed benefits had declined over the boomers' employment years, many are working longer than they had planned.

What lies ahead as each year, millions of members of this gigantic population bulge transition to late adulthood? Most analysts focus on societal burdens, such as rising social security and health-care costs. At the same time, aging boomers have more relevant experience in caring about their world—and more years left to do so—than any previous cohort of older adults. Rather than slowing down in their sixties and seventies, many remain immersed in their careers, start new businesses, or pursue challenging volunteer and service roles (Farrell, 2014). As the boomers cast aside traditional retirement, they are redefining the last third of life as a time of continued engagement, meaning, and contributions to society.

The theory emphasized two related principles: *natural selection* and *survival of the fittest*. Darwin explained that certain species survive in particular environments because they have characteristics that fit with, or are adapted to, their surroundings. Other species die off because they are less well-suited to their environments. Individuals within a species who best meet the environment's survival requirements live long enough to reproduce and pass their more beneficial characteristics to future generations. Darwin's (1859/1936) emphasis on the adaptive value of physical characteristics and behavior found its way into important developmental theories.

During his explorations, Darwin discovered that early prenatal growth is strikingly similar in many species. Other scientists concluded from Darwin's observations that the development of the human child follows the same general plan as the evolution

Darwin's theory of evolution emphasizes the adaptive value of physical characteristics and behavior. Affection and care in families promote survival and psychological well-being throughout the lifespan. Here, a granddaughter shares a moment of intimacy with her grandmother.

THOMAS TOLSTRUP/GETTY IMAGES

of the human species. Although this belief eventually proved inaccurate, efforts to chart parallels between child growth and human evolution prompted researchers to make careful observations of all aspects of children's behavior. Out of these first attempts to document an idea about development, scientific child study was born.

## The Normative Period

G. Stanley Hall (1844–1924), one of the most influential American psychologists of the early twentieth century, is generally regarded as the founder of the child study movement (Cairns & Cairns, 2006). He also foreshadowed lifespan research by writing one of the few books of his time on aging. Inspired by Darwin's work, Hall and his well-known student Arnold Gesell (1880–1961) devised theories based on evolutionary ideas. They regarded development as a *maturational process*—a genetically determined series of events that unfold automatically, much like a flower (Gesell, 1933; Hall, 1904).

Hall and Gesell are remembered less for their one-sided theories than for their intensive efforts to describe all aspects of development. They launched the **normative approach**, in which measures of behavior are taken on large numbers of individuals, and age-related averages are computed to represent typical development. Using this procedure, Hall constructed elaborate questionnaires asking children of different ages almost everything they could tell about themselves—interests, fears, imaginary playmates, dreams, friendships, everyday knowledge, and more. Similarly, through careful observations and parent interviews, Gesell collected detailed normative information on the motor achievements, social behaviors, and personality characteristics of infants and children.

Gesell was also among the first to make knowledge about child development meaningful to parents by informing them of what to expect at each age. If, as he believed, the timetable of development is the product of millions of years of evolution, then children are naturally knowledgeable about their needs. His child-rearing advice recommended sensitivity to children's cues. Along with Benjamin Spock's *Baby and Child Care*, Gesell's books became a central part of a rapidly expanding child development literature for parents.

## The Mental Testing Movement

While Hall and Gesell were developing their theories and methods in the United States, French psychologist Alfred Binet (1857–1911) was also taking a normative approach to child development, but for a different reason. In the early 1900s, Binet and his colleague Theodore Simon were asked by Paris school officials to find a way to identify children with learning problems who needed to be placed in special classes. To address these practical educational concerns, Binet and Simon constructed the first successful intelligence test.

In 1916, at Stanford University, Binet's test was adapted for use with English-speaking children. Since then, the English version has been known as the *Stanford-Binet Intelligence Scale*.

Besides providing a score that could successfully predict school achievement, the Binet test sparked tremendous interest in individual differences in development. Comparisons of the scores of people who vary in gender, ethnicity, birth order, family background, and other characteristics became a major focus of research. And intelligence tests moved quickly to the forefront of the nature–nurture controversy.

## Mid-Twentieth-Century Theories

**1.5** What theories influenced human development research in the mid-twentieth century?

In the mid-twentieth century, the study of human development expanded into a legitimate discipline. A variety of theories emerged, each of which continues to have followers today. In these theories, the European concern with the individual's inner thoughts and feelings contrasts sharply with the North American academic focus on scientific precision and concrete, observable behavior.

## The Psychoanalytic Perspective

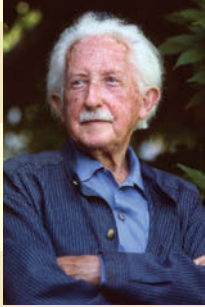

In the 1930s and 1940s, as more people sought help from professionals to deal with emotional difficulties, a new question had to be addressed: How and why do people become the way they are? To treat psychological problems, psychiatrists and social workers turned to an emerging approach to personality development that emphasized each individual's unique life history.

According to the **psychoanalytic perspective**, people move through a series of stages in which they confront conflicts between biological drives and social expectations. How these conflicts are resolved determines the person's ability to learn, to get along with others, and to cope with anxiety. Among the many individuals who contributed to the psychoanalytic perspective, two were especially influential: Sigmund Freud, founder of the psychoanalytic movement, and Erik Erikson.

**Freud's Theory.** Freud (1856–1939), a Viennese physician, sought a cure for emotionally troubled adults by having them talk freely about painful events of their childhoods. Working with these recollections, he examined his patients' unconscious motivations and constructed his **psychosexual theory**, which emphasizes that how parents manage their child's sexual and aggressive drives in the first few years is crucial for healthy personality development.

In Freud's theory, three parts of the personality—*id*, *ego*, and *superego*—become integrated during five stages, summarized in Table 1.2. The *id*, the largest portion of the mind, is the source of basic biological needs and desires. The *ego*, the conscious, rational part of personality, emerges in early infancy to redirect the *id*'s impulses so they are discharged in acceptable ways. Between

**TABLE 1.2**  
**Freud's Psychosexual Stages and Erikson's Psychosocial Stages Compared**

APPROXIMATE AGE	FREUD'S PSYCHOSEXUAL STAGE	ERIKSON'S PSYCHOSOCIAL STAGE
Birth–1 year	<i>Oral</i> : If oral needs are not met through sucking from breast or bottle, the individual may develop such habits as thumb sucking, fingernail biting, overeating, or smoking.	<i>Basic trust versus mistrust</i> : From warm, responsive care, infants gain a sense of trust, or confidence, that the world is good. Mistrust occurs if infants are neglected or handled harshly.
1–3 years	<i>Anal</i> : Toddlers and preschoolers enjoy holding and releasing urine and feces. If parents toilet train before children are ready or make too few demands, conflicts about anal control may appear in the form of extreme orderliness or disorder.	<i>Autonomy versus shame and doubt</i> : Using new mental and motor skills, children want to decide for themselves. Parents can foster autonomy by permitting reasonable free choice and not forcing or shaming the child.
3–6 years	<i>Phallic</i> : As preschoolers take pleasure in genital stimulation, Freud's Oedipus conflict for boys and Electra conflict for girls arise: Children feel a sexual desire for the other-sex parent. To avoid punishment, they give up this desire and adopt the same-sex parent's characteristics and values. As a result, the superego is formed, and children feel guilty when they violate its standards.	<i>Initiative versus guilt</i> : Through make-believe play, children gain insight into the person they can become. Initiative—a sense of ambition and responsibility—develops when parents support their child's sense of purpose. If parents demand too much self-control, children experience excessive guilt.
6–11 years	<i>Latency</i> : Sexual instincts die down, and the superego strengthens as children acquire new social values from adults and same-sex peers.	<i>Industry versus inferiority</i> : At school, children learn to work and cooperate with others. Inferiority develops when negative experiences at home, at school, or with peers lead to feelings of incompetence.
Adolescence	<i>Genital</i> : With puberty, sexual impulses reappear. Successful development during earlier stages leads to marriage, mature sexuality, and child rearing.	<i>Identity versus role confusion</i> : By exploring values and vocational goals, young people form a personal identity. The negative outcome is confusion about future adult roles.
Early adulthood	 <p>© JON ERIKSON/THE IMAGE WORKS</p> <p>I Erik Erikson</p>	<i>Intimacy versus isolation</i> : Young adults establish intimate relationships. Because of earlier disappointments, some individuals cannot form close bonds and remain isolated.
Middle adulthood		<i>Generativity versus stagnation</i> : Generativity means giving to the next generation through child rearing, caring for others, or productive work. The person who fails in these ways feels an absence of meaningful accomplishment.
Old age		<i>Integrity versus despair</i> : Integrity results from feeling that life was worth living as it happened. Older people who are dissatisfied with their lives fear death.

3 and 6 years of age, the *superego*, or conscience, develops as parents insist that children conform to the values of society. Now the ego faces the increasingly complex task of reconciling the demands of the id, the external world, and conscience—for example, the id impulse to grab an attractive toy from a playmate versus the superego's warning that such behavior is wrong. According to Freud, the relations established among id, ego, and superego during the preschool years determine the individual's basic personality.

Freud (1938/1973) believed that during childhood, sexual impulses shift their focus from the oral to the anal to the genital regions of the body. In each stage, parents walk a fine line between permitting too much or too little gratification of their child's basic needs. If parents strike an appropriate balance, children grow into well-adjusted adults with the capacity for mature sexual behavior and investment in family life.

Freud's theory was the first to stress the influence of the early parent–child relationship on development. But his perspec-

tive was eventually criticized. First, it overemphasized the influence of sexual feelings in development. Second, because it was based on the problems of sexually repressed, well-to-do adults in nineteenth-century Victorian society, it did not apply in other cultures. Finally, Freud had not studied children directly.

**Erikson's Theory.** Several of Freud's followers took what was useful from his theory and improved on his vision. The most important is Erik Erikson (1902–1994), who expanded the picture of development at each stage. In his **psychosocial theory**, Erikson emphasized that in addition to mediating between id impulses and superego demands, the ego makes a positive contribution to development, acquiring attitudes and skills that make the individual an active, contributing member of society. A basic psychosocial conflict, which is resolved along a continuum from positive to negative, determines healthy or maladaptive outcomes at each stage. As Table 1.2 shows, Erikson's first five stages parallel Freud's stages, but Erikson added three adult stages.

ANTONIA TOZER/GETTY IMAGES/AWL IMAGES RM

A child of the Kazakh people of Mongolia learns from her grandfather how to train an eagle to hunt small animals, essential for the meat-based Kazakh diet. As Erikson recognized, this parenting practice is best understood in relation to the competencies valued and needed in Kazakh culture.

Unlike Freud, Erikson pointed out that normal development must be understood in relation to each culture's life situation. For example, in the 1940s, he observed that Yurok Indians of the northwest coast of the United States deprived newborns of breastfeeding for the first 10 days, instead feeding them a thin soup. At age 6 months, infants were abruptly weaned—if necessary, by having the mother leave for a few days. From our cultural vantage point, these practices seem cruel. But Erikson explained that because the Yurok depended on salmon, which fill the river just once a year, the development of self-restraint was essential for survival. In this way, he showed that child rearing is responsive to the competencies valued and needed by an individual's society.

**Contributions and Limitations of the Psychoanalytic Perspective.** A special strength of the psychoanalytic perspective is its emphasis on the individual's unique life history as worthy of study and understanding. Consistent with this view, psychoanalytic theorists accept the *clinical*, or *case study*, *method*, which synthesizes information from a variety of sources into a detailed picture of the personality of a single person. (We will discuss this method further at the end of this chapter.) Psychoanalytic theory has also inspired a wealth of research on many aspects of emotional and social development, including infant–caregiver attachment, aggression, sibling relationships, child-rearing practices, morality, gender roles, and adolescent identity.

Despite its extensive contributions, the psychoanalytic perspective is no longer in the mainstream of human development research. Psychoanalytic theorists may have become isolated from the rest of the field because they were so strongly

committed to in-depth study of individuals that they failed to consider other methods. In addition, many psychoanalytic ideas, such as psychosexual stages and ego functioning, are too vague to be tested empirically (Crain, 2010).

Nevertheless, Erikson's broad outline of lifespan change captures key, optimal psychosocial attainments during each major period of the life course. We will return to it, along with other perspectives inspired by Erikson's theory, in later chapters.

## Behaviorism and Social Learning Theory

As the psychoanalytic perspective gained in prominence, the study of development was also influenced by a very different perspective. According to **behaviorism**, directly observable events—stimuli and responses—are the appropriate focus of study. North American behaviorism began in the early twentieth century with the work of John Watson (1878–1958), who wanted to create an objective science of psychology.

**Traditional Behaviorism.** Watson was inspired by Russian physiologist Ivan Pavlov's studies of animal learning. Pavlov knew that dogs release saliva as an innate reflex when they are given food. But he noticed that his dogs were salivating before they tasted any food—when they saw the trainer who usually fed them. The dogs, Pavlov reasoned, must have learned to associate a neutral stimulus (the trainer) with another stimulus (food) that produces a reflexive response (salivation). Because of this association, the neutral stimulus alone could bring about a response resembling the reflex. Eager to test this idea, Pavlov successfully taught dogs to salivate at the sound of a bell by pairing it with the presentation of food. He had discovered *classical conditioning*.

Watson wanted to find out if classical conditioning could be applied to children's behavior. In a historic experiment, he taught Albert, an 11-month-old infant, to fear a neutral stimulus—a soft white rat—by presenting it several times with a sharp, loud sound, which naturally scared the baby. Little Albert, who at first had reached out eagerly to touch the furry rat, began to cry and retreat at the sight of it (Watson & Raynor, 1920). In fact, Albert's fear was so intense that researchers eventually challenged the ethics of studies like this one. Watson concluded that environment is the supreme force in development and that adults can mold children's behavior by carefully controlling stimulus–response associations. He viewed development as continuous—a gradual increase with age in the number and strength of these associations.

Another form of behaviorism was B. F. Skinner's (1904–1990) *operant conditioning theory*. According to Skinner, the frequency of a behavior can be increased by following it with a wide variety of *reinforcers*, such as food, praise, or a friendly smile, or decreased through *punishment*, such as disapproval or withdrawal of privileges. As a result of Skinner's work, operant conditioning became a broadly applied learning principle. We will consider these basic learning capacities further in Chapter 4.

**Social Learning Theory.** Psychologists wondered whether behaviorism might offer a more direct and effective explanation of the development of social behavior than the less precise concepts of psychoanalytic theory. This sparked approaches that built on the principles of conditioning, providing expanded views of how children and adults acquire new responses.

Several kinds of **social learning theory** emerged. The most influential, devised by Albert Bandura (1925– ), emphasizes *modeling*, also known as *imitation* or *observational learning*, as a powerful source of development. The baby who claps her hands after her mother does so, the child who angrily hits a playmate in the same way that he has been punished at home, and the teenager who wears the same clothes and hairstyle as her friends at school are all displaying observational learning. In his early work, Bandura found that diverse factors affect children’s motivation to imitate: their own history of reinforcement or punishment for the behavior, the promise of future reinforcement or punishment, and even observations of the model being reinforced or punished.

Bandura’s work continues to influence much research on social development. But today, his theory stresses the importance of *cognition*, or thinking. In fact, the most recent revision of Bandura’s (1992, 2001) theory places such strong emphasis on how we think about ourselves and other people that he calls it a *social-cognitive* rather than a social learning approach.

In Bandura’s revised view, children gradually become more selective in what they imitate. From watching others engage in self-praise and self-blame and through feedback about the worth of their own actions, children develop *personal standards* for behavior and a *sense of self-efficacy*—the belief that their own abilities and characteristics will help them succeed. These cognitions guide responses in particular situations (Bandura, 2001, 2011). For example, imagine a parent who often remarks, “I’m glad I kept working on that task, even though it was hard,” and

who encourages persistence by saying, “I know you can do a good job on that homework!” Soon the child starts to view herself as hardworking and high-achieving and selects people with these characteristics as models. In this way, as individuals acquire attitudes, values, and convictions about themselves, they control their own learning and behavior.

### Contributions and Limitations of Behaviorism and Social Learning Theory.

Behaviorism and social learning theory have been helpful in treating a wide range of adjustment problems. **Applied behavior analysis** consists of careful observations of individual behavior and related environmental events, followed by systematic changes in those events based on procedures of conditioning and modeling. The goal is to eliminate undesirable behaviors and increase desirable responses. It has been used to relieve a wide range of difficulties in children and adults, ranging from poor time management and unwanted habits to serious problems, such as language delays, persistent aggression, and extreme fears (Heron, Heward, & Cooper, 2013).

Nevertheless, many theorists believe that behaviorism and social learning theory offer too narrow a view of important environmental influences, which extend beyond immediate reinforcement, punishment, and modeled behaviors to people’s rich physical and social worlds. Behaviorism and social learning theory have also been criticized for underestimating people’s contributions to their own development. Bandura, with his emphasis on cognition, is unique among theorists whose work grew out of the behaviorist tradition in granting children and adults an active role in their own learning.

## Piaget’s Cognitive-Developmental Theory

If one individual has influenced research on child development more than any other, it is Swiss cognitive theorist Jean Piaget (1896–1980). North American investigators had been aware of Piaget’s work since 1930. But they did not grant it much attention until the 1960s, mainly because Piaget’s ideas were at odds with behaviorism, which dominated North American psychology in the mid-twentieth century (Watrin & Darwich, 2012). Piaget did not believe that children’s learning depends on reinforcers, such as rewards from adults. According to his **cognitive-developmental theory**, children actively construct knowledge as they manipulate and explore their world.

**Piaget’s Stages.** Piaget’s view of development was greatly influenced by his early training in biology. Central to his theory is the biological concept of *adaptation* (Piaget, 1971). Just as structures of the body are adapted to fit with the environment, so structures of the mind develop to better fit with, or represent, the external world. In infancy and early childhood, Piaget claimed, children’s understanding is different from adults’. For example, he believed that young babies do not realize that an object hidden from view—a favorite toy or even the mother—continues to exist. He also concluded that preschoolers’ thinking is full of

© LAURA DWIGHT PHOTOGRAPHY

Social learning theory recognizes that children acquire many skills through modeling. By observing and imitating his father’s behavior, this child learns an important skill.

**TABLE 1.3**  
**Piaget's Stages of Cognitive Development**

STAGE	PERIOD OF DEVELOPMENT	DESCRIPTION
Sensorimotor	Birth–2 years	Infants “think” by acting on the world with their eyes, ears, hands, and mouth. As a result, they invent ways of solving sensorimotor problems, such as pulling a lever to hear the sound of a music box, finding hidden toys, and putting objects into and taking them out of containers.
Preoperational	2–7 years	Preschool children use symbols to represent their earlier sensorimotor discoveries. Development of language and make-believe play takes place. However, thinking lacks the logic of the two remaining stages.
Concrete operational	7–11 years	Children’s reasoning becomes logical and better organized. School-age children understand that a certain amount of lemonade or play dough remains the same even after its appearance changes. They also organize objects into hierarchies of classes and subclasses. However, children think in a logical, organized fashion only when dealing with concrete information they can perceive directly.
Formal operational	11 years on	The capacity for abstract, systematic thinking enables adolescents, when faced with a problem, to start with a hypothesis, deduce testable inferences, and isolate and combine variables to see which inferences are confirmed. Adolescents can also evaluate the logic of verbal statements without referring to real-world circumstances.

! Jean Piaget

faulty logic. For example, children younger than age 7 commonly say that the amount of a liquid changes when it is poured into a different-shaped container. According to Piaget, children eventually revise these incorrect ideas in their ongoing efforts to achieve

an *equilibrium*, or balance, between internal structures and information they encounter in their everyday worlds.

In Piaget’s theory, as the brain develops and children’s experiences expand, they move through four broad stages, each characterized by qualitatively distinct ways of thinking. Table 1.3 provides a brief description of Piaget’s stages. Cognitive development begins in the *sensorimotor stage* with the baby’s use of the senses and movements to explore the world. These action patterns evolve into the symbolic but illogical thinking of the preschooler in the *preoperational stage*. Then cognition is transformed into the more organized, logical reasoning of the school-age child in the *concrete operational stage*. Finally, in the *formal operational stage*, thought becomes the abstract, systematic reasoning system of the adolescent and adult.

Piaget devised special methods for investigating how children think. Early in his career, he carefully observed his three infant children and presented them with everyday problems, such as an attractive object that could be grasped, mouthed, kicked, or searched for. From their responses, Piaget derived his ideas about cognitive changes during the first two years. To study childhood and adolescent thought, Piaget adapted the clinical method of psychoanalysis, conducting open-ended *clinical interviews* in which a child’s initial response to a task served as the basis for Piaget’s next question. We will look more closely at this technique when we discuss research methods later in this chapter.

### Contributions and Limitations of Piaget’s Theory.

Piaget convinced the field that children are active learners whose minds consist of rich structures of knowledge. Besides investigating children’s understanding of the physical world, Piaget explored their reasoning about the social world. His stages have

© JIM WEST/THE IMAGE WORKS

In Piaget’s formal operational stage, adolescents think systematically and abstractly. These high school students participating in a robotics competition solve problems by generating hypotheses about procedures that might work and conducting systematic tests to observe their real-world consequences.

sparked a wealth of research on children’s conceptions of themselves, other people, and human relationships. In practical terms, Piaget’s theory encouraged the development of educational philosophies and programs that emphasize discovery learning and direct contact with the environment.

Despite Piaget’s overwhelming contributions, his theory has been challenged. Research indicates that Piaget underestimated the competencies of infants and preschoolers. When young children are given tasks scaled down in difficulty and relevant to their everyday experiences, their understanding appears closer to that of the older child and adult than Piaget assumed. Also, adolescents generally reach their full intellectual potential only in areas of endeavor in which they have had extensive education and experience. These findings have led many researchers to conclude that cognitive maturity depends heavily on the complexity of knowledge sampled and the individual’s familiarity with the task (Miller, 2011).

Furthermore, children’s performance on Piagetian problems can be improved with training—findings that call into question Piaget’s assumption that discovery learning rather than adult teaching is the best way to foster development (Klahr, Matlen, & Jirout, 2013; Siegler & Svetina, 2006). Critics also point out that Piaget’s stagewise account pays insufficient attention to social and cultural influences on development. Finally, lifespan theorists—challenging Piaget’s conclusion that no new stages occur after adolescence—have proposed important transformations in adulthood (Heckhausen, Wrosch, & Schulz, 2010; ; Moshman, 2011; Perry, 1970/1998).

Today, the field of developmental science is divided over its loyalty to Piaget’s ideas. Those who continue to find merit in Piaget’s stages often accept a modified view—one in which changes in thinking take place more gradually than Piaget believed (Case, 1998; Halford & Andrews, 2011; Mascolo & Fischer, 2015). Among those who disagree with Piaget’s stage sequence, some have embraced an approach that emphasizes continuous gains in children’s cognition: information processing. And still others have been drawn to theories that focus on the role of children’s social and cultural contexts. We take up these approaches in the next section.

## Ask yourself

**CONNECT** Although social learning theory focuses on social development and Piaget’s theory on cognitive development, each has enhanced our understanding of other domains. Mention an additional domain addressed by each theory.

**APPLY** A 4-year-old becomes frightened of the dark and refuses to go to sleep at night. How would a psychoanalyst and a behaviorist differ in their views of how this problem developed?

**REFLECT** Illustrate Bandura’s ideas by describing a personal experience in which you observed and received feedback from another person that strengthened your sense of self-efficacy—belief that your abilities and characteristics will help you succeed.

## Recent Theoretical Perspectives

**1.6** Describe recent theoretical perspectives on human development.

New ways of understanding the developing person are constantly emerging—questioning, building on, and enhancing the discoveries of earlier theories. Today, a wealth of fresh approaches and research emphases is broadening our insights into lifespan development.

### Information Processing

In the 1970s and 1980s, researchers turned to the field of cognitive psychology for ways to understand the development of thinking. The design of digital computers that use mathematically specified steps to solve problems suggested to psychologists that the human mind might also be viewed as a symbol-manipulating system through which information flows—a perspective called **information processing** (Munakata, 2006). From the time information is presented to the senses at *input* until it emerges as a behavioral response at *output*, information is actively coded, transformed, and organized.

Information-processing researchers often design flowcharts to map the precise steps individuals use to solve problems and complete tasks, much like the plans devised by programmers to get computers to perform a series of “mental operations.” They seek to clarify how both task characteristics and cognitive limitations—for example, memory capacity or available knowledge—influence performance (Birney & Sternberg, 2011). To see the usefulness of this approach, let’s look at an example.

In a study of problem solving, a researcher provided a pile of blocks varying in size, shape, and weight and asked school-age children to build a bridge across a “river” (painted on a floor mat) that was too wide for any single block to span (Thornton, 1999). Figure 1.4 shows one solution: Two planklike blocks span the water, each held in place by the counterweight of heavy blocks on the bridge’s towers. Whereas older children easily built successful bridges, only one 5-year-old did. Careful tracking of her efforts revealed that she repeatedly tried unsuccessful strategies, such as pushing two planks together and pressing down on their ends to hold them in place. But eventually, her experimentation triggered the idea of using the blocks as counterweights. Her mistaken procedures helped her understand why the counterweight approach worked.

Many information-processing models exist. Some, like the one just considered, track mastery of one or a few tasks. Others describe the human cognitive system as a whole (Gopnik & Tenenbaum, 2007; Ristic & Enns, 2015; Westermann et al., 2006). These general models are used as guides for asking questions about broad changes in thinking: Does a child’s ability to solve problems become more organized and “planful” with age? Why is information processing slower among older than younger

**FIGURE 1.4** Information-processing flowchart showing the steps that a 5-year-old used to solve a bridge-building problem. Her task was to use blocks varying in size, shape, and weight, some of which were planklike, to construct a bridge across a “river” (painted on a floor mat) too wide for any single block to span. The child discovered how to counterweight and balance the bridge. The arrows reveal that, even after building a successful counterweight, she returned to earlier, unsuccessful strategies, which seemed to help her understand why the counterweight approach worked. (Based on Thornton, 1999.)

adults? Are declines in memory during old age evident on all types of tasks or only some?

Like Piaget’s theory, the information-processing approach regards people as actively making sense of their own thinking (Halford & Andrews, 2011; Munakata, 2006). But unlike Piaget’s theory, it does not divide development into stages. Rather, most information-processing researchers regard the thought processes studied—perception, attention, memory, categorization of information, planning, problem solving, and comprehension of written and spoken prose—as similar at all ages but present to a lesser or greater extent. Their view of development is one of continuous change.

A great strength of the information-processing approach is its commitment to rigorous research methods. Because it has provided precise accounts of how children and adults tackle many cognitive tasks, its findings have important implications for education. Currently, researchers are intensely interested in the development of an array of “executive” processes that enable children and adults to manage their thoughts, emotions, and actions. These capacities—variously labeled self-control, self-regulation, executive function, planning, delay of gratification, and more—are essential for attaining our goals in challenging situations (Carlson, Zelazo, & Faja, 2013; Chevalier, 2015; Müller & Kerns, 2015). As we will see in later chapters, executive processes are consistent predictors of academic achievement, socially competent behavior, life success, and psychological well-being.

Nevertheless, information processing has fallen short in some respects. It has been better at analyzing thinking into its components than at putting them back together into a comprehensive theory. And it has had little to say about aspects of cognition that are not linear and logical, such as imagination and creativity.

## Developmental Neuroscience

Over the past three decades, as information-processing research expanded, a new area of investigation arose called **developmental**

**cognitive neuroscience**. It brings together researchers from psychology, biology, neuroscience, and medicine to study the relationship between changes in the brain and the developing person’s cognitive processing and behavior patterns.

Improved methods for analyzing brain activity while children and adults perform various tasks have greatly enhanced knowledge of relationships between brain functioning and behavior (de Haan, 2015). Armed with these brain electrical-recording and imaging techniques (which we will consider in Chapter 4), neuroscientists are tackling questions like these: How does genetic makeup combine with specific experiences at various ages to influence development and organization of the brain? What transformations in the brain make it harder for adolescents and adults than for children to acquire a second language? What neurological changes are related to declines in speed of thinking, memory, and other aspects of cognitive processing in late adulthood?

A complementary new area, **developmental social neuroscience**, is devoted to studying the relationship between changes in the brain and emotional and social development. Developmental social neuroscience emerged later than its cognitive counterpart because techniques for measuring brain activity are hard to implement in most social situations, where children and adults must move freely to interact with others (Zelazo & Paus, 2010). When researchers started to tap more convenient neurobiological measures that are sensitive to psychological state, such as heart rate, blood pressure, and hormone levels detected in saliva, an explosion of social-neuroscience investigations followed.

Active areas of investigation in developmental social neuroscience include identification of the neural systems underlying infants’ capacity to imitate others, adolescents’ heightened risk-taking behavior, and individual differences in impulsivity, sociability, anxiety, aggression, and depression. One particularly energetic focus is the negative impact of extreme adversity, such as early rearing in deprived orphanages or child abuse and neglect, on brain development and cognitive, emotional, and social skills (Anderson & Beauchamp, 2013; Gunnar, Doom, &

© LAURA DWIGHT PHOTOGRAPHY

A therapist encourages a 6-year-old with autism to master the alphabet and interact socially, giving her a high five for progress. Developmental social neuroscientists are intensely interested in identifying the neurological bases of autism and using those findings to devise effective interventions.

Esposito, 2015). Another burgeoning interest is uncovering the neurological bases of *autism*—the disrupted brain structures and networks that lead to the impaired social skills, language delays, and repetitive motor behavior of this disorder (Stoner et al., 2014). As these efforts illustrate, researchers are forging links between cognitive and social neuroscience, identifying brain systems that affect both domains of development.

Rapid progress in clarifying the types of experiences that support or undermine brain development at diverse ages is contributing to effective interventions for enhancing cognitive and social functioning. Today, researchers are examining the impact of various training and treatment techniques on both brain functioning and behavior (Johnson & de Haan, 2015; Lustig & Lin, 2016). Although much remains to be discovered, developmental neuroscience is broadening our understanding of development and yielding major practical applications throughout the lifespan.

Nevertheless, neuroscience research has so captivated the field that it poses the risk that brain properties underlying human behavior will be granted undue importance over powerful environmental influences, such as parenting, education, and economic inequalities in families and communities. Although most neuroscientists are mindful of the complex interplay among heredity, individual experiences, and brain development, their findings have too often resulted in excessive emphasis being placed on biological processes (Kagan, 2013b).

Fortunately, an advantage of having many theories is that they encourage researchers to attend to previously neglected dimensions of people's lives. The final three perspectives we will discuss focus on *contexts* for development. The first of these views emphasizes that the environments to which humans have been exposed over their long evolutionary history influences the development of many capacities.

## Ethology and Evolutionary Developmental Psychology

**Ethology** is concerned with the adaptive, or survival, value of behavior and its evolutionary history. Its roots can be traced to the work of Darwin. Two European zoologists, Konrad Lorenz and Niko Tinbergen, laid its modern foundations. Watching diverse animal species in their natural habitats, Lorenz and Tinbergen observed behavior patterns that promote survival. The best known of these is *imprinting*, the early following behavior of certain baby birds, such as geese, that ensures that the young will stay close to the mother and be fed and protected from danger. Imprinting takes place during an early, restricted period of development (Lorenz, 1952). If the mother goose is absent during this time but an object resembling her in important features is present, young goslings may imprint on it instead.

Observations of imprinting led to a major concept in human development: the *critical period*. It is a limited time span during which the individual is biologically prepared to acquire certain adaptive behaviors but needs the support of an appropriately stimulating environment. Many researchers have investigated whether complex cognitive and social behaviors must be learned during certain time periods. For example, if children are deprived of adequate food or physical and social stimulation during their early years, will their intelligence be impaired? If language is not mastered in early childhood, is the child's capacity to acquire it reduced?

In later chapters, we will see that the term *sensitive period* applies better to human development than the strict notion of a critical period (Knudsen, 2004). A **sensitive period** is a time that is biologically optimal for certain capacities to emerge because the individual is especially responsive to environmental influences. However, its boundaries are less well-defined than those of a critical period. Development can occur later, but it is harder to induce.

MARTIN HARVEY/GETTY IMAGES/PETER ARNOLD

Ethology focuses on the adaptive, or survival, value of behavior and on similarities between human behavior and that of other species, especially our primate relatives. Observing this chimpanzee mother cuddling her infant helps us understand the human caregiver–infant relationship.

Inspired by observations of imprinting, British psychoanalyst John Bowlby (1969) applied ethological theory to the understanding of the human infant–caregiver relationship. He argued that infant smiling, babbling, grasping, and crying are built-in social signals that encourage the caregiver to approach, care for, and interact with the baby. By keeping the parent near, these behaviors help ensure that the infant will be fed, protected from danger, and provided with stimulation and affection necessary for healthy growth. The development of attachment in humans is a lengthy process involving psychological changes that lead the baby to form a deep affectionate tie with the caregiver (Thompson, 2006). Bowlby believed that this bond has lifelong consequences for human relationships. In later chapters, we will consider research that evaluates this assumption.

Observations by ethologists have shown that many aspects of social behavior, including emotional expressions, aggression, cooperation, and social play, resemble those of our primate relatives. Recently, researchers have extended this effort in a new area of research called **evolutionary developmental psychology**. It seeks to understand the adaptive value of species-wide cognitive, emotional, and social competencies as those competencies change with age (King & Bjorklund, 2010; Lickliter & Honeycutt, 2013). Evolutionary developmental psychologists ask questions like these: What role does the newborn’s visual preference for facelike stimuli play in survival? Does it support older infants’ capacity to distinguish familiar caregivers from unfamiliar people? Why do children play in gender-segregated groups? What do they learn from such play that might lead to adult gender-typed behaviors, such as male dominance and female investment in caregiving?

As these examples suggest, evolutionary psychologists are not just concerned with the genetic and biological roots of development. They recognize that humans’ large brain and extended

childhood resulted from the need to master an increasingly complex environment, so they are also interested in learning (Bjorklund, Causey, & Periss, 2009). And they realize that today’s lifestyles differ so radically from those of our evolutionary ancestors that certain evolved behaviors—such as life-threatening risk taking in adolescents and male-to-male violence—are no longer adaptive (Blasi & Bjorklund, 2003).

Recently, evolutionary psychologists have begun to address the adaptiveness of human longevity—why adults live as much as one-fourth to one-third of their years after their children are grown (Croft et al., 2015). A common explanation involves the support that grandparents (especially grandmothers) offer in rearing young grandchildren, which is associated with higher birth and child-survival rates. Another emphasizes the scarcity of group resources that resulted when, in our evolutionary past, both younger and older females could reproduce, with costs for child survival.

In sum, evolutionary developmental psychology aims to understand the *person–environment system* throughout the lifespan. The next contextual perspective we will discuss, Vygotsky’s sociocultural theory, serves as an excellent complement to the evolutionary viewpoint because it highlights social and cultural contexts for development.

## Vygotsky’s Sociocultural Theory

The field of developmental science has recently seen a dramatic increase in research demonstrating that human development and culture are closely interwoven (Mistry & Dutta, 2015). The contributions of Russian psychologist Lev Vygotsky (1896–1934) and his followers have played a major role in this trend.

Vygotsky’s (1934/1987) perspective, called **sociocultural theory**, focuses on how *culture*—the values, beliefs, customs, and skills of a social group—is transmitted to the next generation. According to Vygotsky, *social interaction*—in particular, cooperative dialogues with more knowledgeable members of society—is necessary for children to acquire the ways of thinking and behaving that make up a community’s culture. Vygotsky believed that as adults and more expert peers help children master culturally meaningful activities, the communication between them becomes part of children’s thinking. As children internalize the features of these dialogues, they use the language within them to guide their own thought and actions and to acquire new skills (Lourenço, 2012; Winsler, Fernyhough, & Montero, 2009). The young child instructing herself while working a puzzle, preparing a table for dinner, or solving a math problem has begun to produce the same kind of guiding comments that an adult previously used to help her master culturally important tasks.

Vygotsky’s theory has been especially influential in the study of cognitive development. Vygotsky agreed with Piaget that children are active, constructive beings. But whereas Piaget emphasized children’s independent efforts to make sense of their world, Vygotsky viewed cognitive development as a *socially mediated process*, in which children depend on assistance from adults and more expert peers as they tackle new challenges.

© KIDSTOCK/BLEND IMAGES/CORBIS

Human longevity may have adaptive value. Grandparents’ support in rearing young grandchildren promotes higher birth and child-survival rates.

© FLORESCO PRODUCTIONS/CORBIS

With her teacher's guidance, this Chinese child practices calligraphy. She acquires a culturally valued skill through interaction with an older, more experienced calligrapher.

In Vygotsky's theory, children undergo certain stagewise changes. For example, when they acquire language, they gain in ability to participate in dialogues with others, and mastery of culturally valued competencies surges forward. When children enter school, they spend much time discussing language, literacy, and other academic concepts—experiences that encourage them to reflect on their own thinking (Kozulin, 2003). As a result, they advance dramatically in reasoning and problem solving.

At the same time, Vygotsky stressed that dialogues with experts lead to continuous changes in thinking that vary greatly from culture to culture. Consistent with this view, a major finding of cross-cultural research is that cultures select tasks for their members, and social interaction surrounding those tasks leads to competencies essential for success in a particular culture. For example, in industrialized nations, teachers help people learn to read, drive a car, or use a computer. Among the Zinacanteco Indians of southern Mexico, adult experts guide young girls as they master complicated weaving techniques (Greenfield, 2004). In Brazil and other developing nations, child candy sellers with little or no schooling develop sophisticated mathematical abilities as the result of buying candy from wholesalers, pricing it in collaboration with adults and experienced peers, and bargaining with customers on city streets (Saxe, 1988).

Research stimulated by Vygotsky's theory reveals that people in every culture develop unique strengths. But Vygotsky's emphasis on culture and social experience led him to neglect the biological side of development. Although he recognized the importance of heredity and brain growth, he said little about their role in cognitive change. Furthermore, Vygotsky's focus on social transmission of knowledge meant that, compared with other theorists, he placed less emphasis on children's capacity to shape their own development. Followers of Vygotsky stress that children strive for social connection, actively participating in the conversations and social activities from which their development springs (Daniels, 2011; Rogoff, 2003). Contemporary sociocultural theorists grant the individual and society more balanced, mutually influential roles.

## Ecological Systems Theory

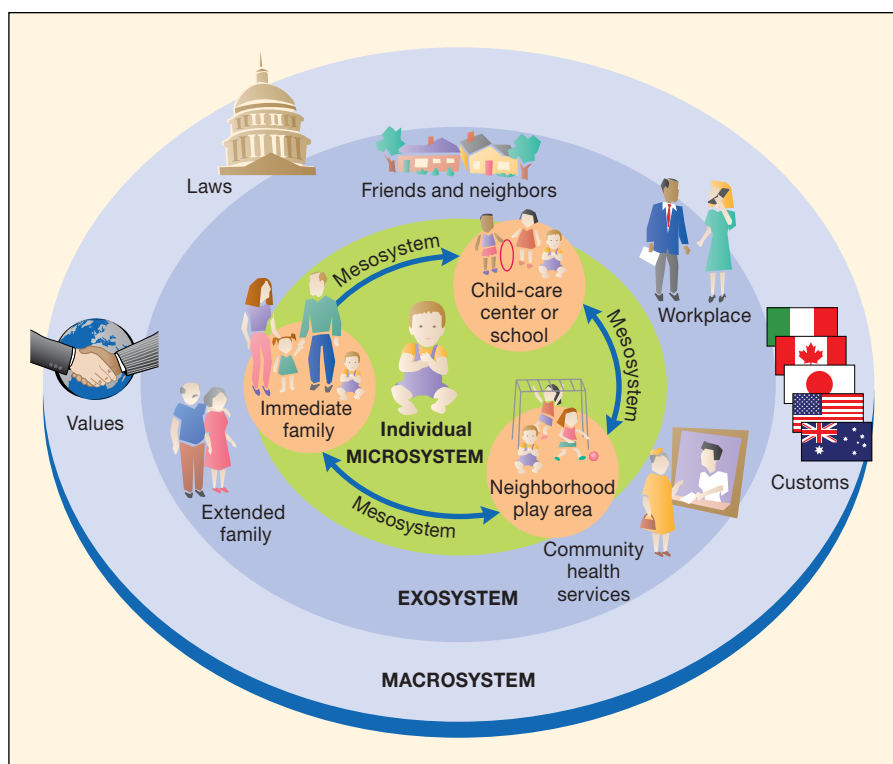

Urie Bronfenbrenner (1917–2005) is responsible for an approach that rose to the forefront of the field because it offers the most differentiated and complete account of contextual influences on development. **Ecological systems theory** views the person as developing within a complex *system* of relationships affected by multiple levels of the surrounding environment. Because the child's biologically influenced dispositions join with environmental forces to mold development, Bronfenbrenner characterized his perspective as a *bioecological model* (Bronfenbrenner & Morris, 2006).

Bronfenbrenner envisioned the environment as a series of nested structures, including but also extending beyond the home, school, neighborhood, and workplace settings in which people spend their everyday lives (see Figure 1.5 on page 24). Each layer joins with the others to powerfully affect development.

**The Microsystem.** The innermost level of the environment, the **microsystem**, consists of activities and interaction patterns in the person's immediate surroundings. Bronfenbrenner emphasized that to understand development at this level, we must keep in mind that all relationships are *bidirectional*: Adults affect children's behavior, but children's biologically and socially influenced characteristics—their physical attributes, personalities, and capacities—also affect adults' behavior. A friendly, attentive child is likely to evoke positive, patient reactions from parents, whereas an irritable or distractible child is more likely to receive impatience, restriction, and punishment. When these reciprocal interactions occur often over time, they have an enduring impact on development (Crockenberg & Leerkes, 2003).

*Third parties*—other individuals in the microsystem—also affect the quality of any two-person relationship. If they are supportive, interaction is enhanced. For example, when parents encourage each other in their child-rearing roles, each engages in more effective parenting. In contrast, marital conflict is associated with inconsistent discipline and hostility toward children. In response, children often react with fear and anxiety or with anger and aggression, and the well-being of both parent and child suffers (Cummings & Davies, 2010; Low & Stocker, 2012).

**FIGURE 1.5 Structure of the environment in ecological systems theory.** The *microsystem* concerns relations between the developing person and the immediate environment; the *mesosystem*, connections among immediate settings; the *exosystem*, social settings that affect but do not contain the developing person; and the *macrosystem*, the values, laws, customs, and resources of the culture that affect activities and interactions at all inner layers. The *chronosystem* (not pictured) is not a specific context. Instead, it refers to the dynamic, ever-changing nature of the person's environment.

**The Mesosystem.** The second level of Bronfenbrenner's model, the **mesosystem**, encompasses connections between microsystems. For example, a child's academic progress depends not just on activities that take place in classrooms but also on parent involvement in school life and on the extent to which academic learning is carried over to the home (Wang & Sheikh-Khalil, 2014). Among adults, how well a person functions as

spouse and parent at home is affected by relationships in the workplace, and vice versa (Strazdins et al., 2013).

**The Exosystem.** The **exosystem** consists of social settings that do not contain the developing person but nevertheless affect experiences in immediate settings. These can be formal organizations, such as the management in the individual's workplace, religious institution, or community health and welfare services. Flexible work schedules, paid maternity and paternity leave, and sick leave for parents whose children are ill are examples of ways that work settings can support child rearing and, indirectly, enhance the development of both adult and child. Exosystem supports can also be informal. Children are affected by their parents' social networks—friends and extended-family members who provide advice, companionship, and even financial assistance. Research confirms the negative impact of a breakdown in exosystem activities. Families who are affected by unemployment or who are socially isolated, with few personal or community-based ties, show increased rates of conflict and child abuse (Tomyr, Ouimet, & Ugnat, 2012). Refer to the Social Issues: Health box on the following page for an additional illustration of the power of the exosystem to affect family functioning and children's development.

A mother says good-bye to her son as she drops him off at preschool. The child's experiences at preschool (microsystem) and the mother's experiences at work (exosystem) affect the parent-child relationship.

**The Macrosystem.** The outermost level of Bronfenbrenner's model, the **macrosystem**, consists of cultural values, laws, customs, and resources. The priority that the macrosystem gives to the needs of children and adults affects the support they receive

## Social Issues: Health

### Family Chaos Undermines Parents' and Children's Well-Being

All of us can recall days during our childhoods when family routines—regular mealtime, bedtime, homework time, and parent–child reading and playtimes—were disrupted, perhaps because of a change in a parent's job, a family illness, or a busy season of after-school sports. In some families, however, absence of daily structure is nearly constant, yielding a chaotic home life that interferes with healthy development (Fiese & Winter, 2010). An organized family life provides a supportive context for warm, involved parent–child interaction, which is essential to both parents' and children's well-being.

Family chaos is linked to economic disadvantage—especially, single mothers with limited incomes struggling to juggle the challenges of transportation, shift jobs, unstable child-care arrangements, and other daily hassles. But chaos is not limited to such families.

Surveys reveal that among U.S. families as a whole, mothers' time with children has remained fairly stable over the past four decades, while fathers' time has increased (Pew Research Center, 2015c). But the way many parents spend that time has changed. Across income levels and ethnic groups, employed mothers and fathers, but especially mothers, report more multitasking while caring for children—for example, preparing dinner while helping with homework, or reading to children while checking work-related emails (Bianchi, 2011; Offer & Schneider, 2011). Mothers who frequently multitask experience greater psychological stress.

Parental multitasking disrupts family routines—a possible reason that today's parents and children often say they have too little time together. For example, only about half of U.S. families report eating meals together regularly (Child Trends, 2013; Opinion Research Corporation, 2009). Frequency of family meals is associated with wide-ranging positive outcomes—in childhood, enhanced language development and academic achievement, fewer behavior problems, and time spent sleeping; and in adolescence, reduced sexual risk taking, alcohol and drug use, and

mental health problems. Shared mealtimes also increase the likelihood of a healthy diet and protect against obesity and adolescent eating disorders (Fiese & Schwartz, 2008; Lora et al., 2014). As these findings suggest, regular mealtimes are a general indicator of an organized family life and positive parent involvement.

But family chaos can prevail even when families do engage in joint activities. Unpredictable, disorganized family routines involving harsh or lax parental discipline and hostile, disrespectful communication are associated with child and adolescent adjustment difficulties (Fiese, Foley, & Spagnola, 2006; Milkie, Nomaguchi, & Denny, 2015). As family time becomes pressured and overwhelming, its orderly structure diminishes, and parental stress escalates while warm parent–child engagement disintegrates.

Diverse circumstances can trigger a pileup of limited parental emotional resources, breeding family chaos. In addition to *micro-system* and *mesosystem* influences (parents with mental health problems, parental separa-

tion and divorce, single parents with few or no supportive relationships), the *exosystem* is powerful: When family time is at the mercy of external forces—parents commuting several hours a day to and from work, child-care arrangements often failing, parents experiencing excessive workplace pressures or job loss—family routines are threatened.

Family chaos contributes to children's behavior problems, above and beyond its negative impact on parenting effectiveness (Fiese & Winter, 2010; Martin, Razza, & Brooks-Gunn, 2012). Chaotic surroundings induce in children a sense of being hassled and feelings of powerlessness, which engender anxiety and low self-esteem.

Exosystem and macrosystem supports—including work settings with favorable family policies and high-quality child care that is affordable and reliable—can help prevent escalating demands on families that give way to chaos. In one community, a child-care center initiated a take-home dinner program. Busy parents could special-order a healthy, reasonably priced family meal, ready to go at day's end to aid in making the family dinner a routine that enhances children's development.

© JANINE WIEDEL/PHOTOLIBRARY/ALAMY

A chaotic home life interferes with warm, relaxed parent–child interaction and contributes to behavior problems. Exosystem influences, such as excessive workplace pressures, can trigger disorganized family routines.

at inner levels of the environment. For example, in countries that require generous workplace benefits for employed parents and set high standards for quality of child care, children are more likely to have favorable experiences in their immediate settings. And when the government provides a generous pension plan for retirees, it supports the well-being of older people.

### LOOK and LISTEN

Ask a parent to explain his or her most worrisome child-rearing challenge. Describe one source of support at each level of Bronfenbrenner's bioecological model that could ease parental stress and promote child development.

**A Dynamic, Ever-Changing System.** According to Bronfenbrenner, the environment is not a static force that affects people in a uniform way. Instead, it is ever-changing. Whenever individuals add or let go of roles or settings in their lives, the breadth of their microsystems changes. These shifts in contexts—*ecological transitions*, as Bronfenbrenner called them—are often important turning points in development. Starting school, entering the workforce, moving in together, marrying, becoming a parent, getting divorced, and retiring are examples.

Bronfenbrenner labeled the temporal dimension of his model the **chronosystem** (the prefix *chrono* means “time”). Life changes can be imposed externally or, alternatively, can arise from within the person, since individuals select, modify, and create many of their own settings and experiences. How they do so depends on their physical, intellectual, and personality characteristics and their environmental opportunities. Therefore, in ecological systems theory, development is neither controlled by environmental circumstances nor driven solely by inner dispositions. Rather, people are both products and producers of their environments: The person and the environment form a network of interdependent effects. Our discussion of resilience on pages 10–11 illustrates this idea. You will see many more examples in later chapters.

### Ask yourself

**CONNECT** Is ecological systems theory compatible with assumptions of the lifespan perspective—development as lifelong, multidirectional, highly plastic, and influenced by multiple, interacting forces? Explain.

**APPLY** Mario wants to find out precisely how children of different ages recall stories. Desiree is interested in how adult–child communication in different cultures influences children's storytelling. Which theoretical perspective has Mario probably chosen? How about Desiree? Explain.

**REFLECT** To illustrate the chronosystem in ecological systems theory, select an important event from your childhood, such as a move to a new neighborhood, a class with an inspiring teacher, or parental divorce. How did the event affect you? How might its impact have differed had you been five years younger? How about five years older?

## Comparing and Evaluating Theories

**1.7** Identify the stand taken by each major theory on the three basic issues of human development.

In the preceding sections, we reviewed major theoretical perspectives in human development research. They differ in many respects. First, they focus on different domains of development. Some, such as the psychoanalytic perspective and ethology, emphasize emotional and social development. Others, such as Piaget's cognitive-developmental theory, information processing, and Vygotsky's sociocultural theory, stress changes in thinking. The remaining approaches—behaviorism, social learning theory, evolutionary developmental psychology, ecological systems theory, and the lifespan perspective—encompass many aspects of human functioning. Second, every theory contains a point of view about development. As we conclude our review of theoretical perspectives, identify the stand that each theory takes on the basic issues discussed at the beginning of this chapter. Then check your analysis against Table 1.4.

Finally, we have seen that every theory has strengths and limitations. Perhaps you are attracted to some theories but have doubts about others. As you read more about development in later chapters, you may find it useful to keep a notebook in which you test your own theoretical likes and dislikes against the evidence. Don't be surprised if you revise your ideas many times, just as theorists have done since scientific study of development began.

## Studying Development

**1.8** Describe methods commonly used in research on human development.

**1.9** Distinguish between correlational and experimental research designs, noting the strengths and limitations of each.

**1.10** Describe designs for studying development, noting the strengths and limitations of each.

In every science, research is usually based on a *hypothesis*—a prediction drawn directly from a theory. Theories and hypotheses, however, merely initiate the many activities that result in sound evidence on human development. Conducting research according to scientifically accepted procedures involves many steps and choices. Investigators must decide which participants, and how many, to include. Then they must figure out what the participants will be asked to do and when, where, and how many times each will be seen. Finally, they must examine and draw conclusions from their data.

In the following sections, we look at research strategies commonly used to study human development. We begin with

**TABLE 1.4**  
**Stances of Major Theories on Basic Issues in Human Development**

THEORY	CONTINUOUS OR DISCONTINUOUS DEVELOPMENT?	ONE COURSE OF DEVELOPMENT OR MANY?	RELATIVE INFLUENCE OF NATURE AND NURTURE?
Psychoanalytic perspective	<i>Discontinuous:</i> Psychosexual and psychosocial development takes place in stages.	<i>One course:</i> Stages are assumed to be universal.	<i>Both nature and nurture:</i> Innate impulses are channeled and controlled through child-rearing experiences. <i>Early experiences</i> set the course of later development.
Behaviorism and social learning theory	<i>Continuous:</i> Development involves an increase in learned behaviors.	<i>Many possible courses:</i> Behaviors reinforced and modeled may vary from person to person.	<i>Emphasis on nurture:</i> Development is the result of conditioning and modeling. <i>Both early and later experiences</i> are important.
Piaget's cognitive-developmental theory	<i>Discontinuous:</i> Cognitive development takes place in stages.	<i>One course:</i> Stages are assumed to be universal.	<i>Both nature and nurture:</i> Development occurs as the brain grows and children exercise their innate drive to discover reality in a generally stimulating environment. <i>Both early and later experiences</i> are important.
Information processing	<i>Continuous:</i> Children and adults change gradually in perception, attention, memory, and problem-solving skills.	<i>One course:</i> Changes studied characterize most or all children and adults.	<i>Both nature and nurture:</i> Children and adults are active, sense-making beings who modify their thinking as the brain grows and they confront new environmental demands. <i>Both early and later experiences</i> are important.
Ethology and evolutionary developmental psychology	<i>Both continuous and discontinuous:</i> Children and adults gradually develop a wider range of adaptive behaviors. Sensitive periods occur in which qualitatively distinct capacities emerge fairly suddenly.	<i>One course:</i> Adaptive behaviors and sensitive periods apply to all members of a species.	<i>Both nature and nurture:</i> Evolution and heredity influence behavior, and learning lends greater flexibility and adaptiveness to it. In sensitive periods, <i>early experiences</i> set the course of later development.
Vygotsky's sociocultural theory	<i>Both continuous and discontinuous:</i> Language acquisition and schooling lead to stagewise changes. Dialogues with more expert members of society also result in continuous changes that vary from culture to culture.	<i>Many possible courses:</i> Socially mediated changes in thought and behavior vary from culture to culture.	<i>Both nature and nurture:</i> Heredity, brain growth, and dialogues with more expert members of society jointly contribute to development. <i>Both early and later experiences</i> are important.
Ecological systems theory	<i>Not specified.</i>	<i>Many possible courses:</i> Biologically influenced dispositions join with environmental forces at multiple levels to mold development in unique ways.	<i>Both nature and nurture:</i> The individual's characteristics and the reactions of others affect each other in a bidirectional fashion. <i>Both early and later experiences</i> are important.
<b>Lifespan perspective</b>	<b><i>Both continuous and discontinuous:</i> Continuous gains and declines and discontinuous, stagewise emergence of new skills occur.</b>	<b><i>Many possible courses:</i> Development is influenced by multiple, interacting biological, psychological, and social forces, many of which vary from person to person, leading to diverse pathways of change.</b>	<b><i>Both nature and nurture:</i> Development is multidimensional, affected by an intricate blend of hereditary and environmental factors. Emphasizes plasticity at all ages. <i>Both early and later experiences</i> are important.</b>

*research methods*—the specific activities of participants, such as taking tests, answering questionnaires, responding to interviews, or being observed. Then we turn to *research designs*—overall plans for research studies that permit the best possible test of the investigator's hypothesis. Finally, we discuss ethical issues involved in doing research with human participants.

Why learn about research strategies? There are two reasons. First, each of us must be a wise and critical consumer of knowledge. Knowing the strengths and limitations of various research strategies is important in separating dependable information

from misleading results. Second, individuals who work directly with children or adults may be in a unique position to build bridges between research and practice by conducting studies, either on their own or in partnership with experienced investigators. Community agencies such as schools, mental health facilities, and parks and recreation programs sometimes collaborate with researchers in designing, implementing, and evaluating interventions aimed at enhancing development (Guerra, Graham, & Tolan, 2011). To broaden these efforts, a basic understanding of the research process is essential.

**LOOK and LISTEN**

Ask a teacher, counselor, social worker, or nurse to describe a question about development he or she would like researchers to address. After reading the rest of this chapter, recommend research strategies best suited to answering that question.

**Common Research Methods**

How does a researcher choose a basic approach to gathering information? Common methods include systematic observation, self-reports (such as questionnaires and interviews), clinical or case studies of a single individual, and ethnographies of the life circumstances of a specific group of people. Table 1.5 summarizes the strengths and limitations of each of these methods.

**Systematic Observation.** Observations of the behavior of children and adults can be made in different ways. One approach is to go into the field, or natural environment, and record the behavior of interest—a method called **naturalistic observation**.

A study of preschoolers' responses to their peers' distress provides a good example (Farver & Branstetter, 1994). Observing 3- and 4-year-olds in child-care centers, the researchers recorded each instance of crying and the reactions of nearby children—whether they ignored, watched, commented on the child's unhappiness, scolded or teased, or shared, helped, or expressed sympathy. Caregiver behaviors—explaining why a child was crying, mediating conflict, or offering comfort—were noted to see if adult sensitivity was related to children's caring responses. A strong relationship emerged. The great strength of naturalistic observation is that investigators can see directly the everyday behaviors they hope to explain.

Naturalistic observation also has a major limitation: Not all individuals have the same opportunity to display a particular behavior in everyday life. In the study just described, some children might have witnessed a child crying more often than others or been exposed to more cues for positive social responses from caregivers. For these reasons, they might have displayed more compassion.

Researchers commonly deal with this difficulty by making **structured observations**, in which the investigator sets up a

**TABLE 1.5**  
**Strengths and Limitations of Common Research Methods**

METHOD	DESCRIPTION	STRENGTHS	LIMITATIONS
<b>SYSTEMATIC OBSERVATION</b>			
Naturalistic observation	Observation of behavior in natural contexts	Reflects participants' everyday lives.	Cannot control conditions under which participants are observed.
Structured observation	Observation of behavior in a laboratory, where conditions are the same for all participants	Grants each participant an equal opportunity to display the behavior of interest.	May not yield observations typical of participants' behavior in everyday life.
<b>SELF-REPORTS</b>			
Clinical interview	Flexible interviewing procedure in which the investigator obtains a complete account of the participant's thoughts	Comes as close as possible to the way participants think in everyday life. Great breadth and depth of information can be obtained in a short time.	May not result in accurate reporting of information. Flexible procedure makes comparing individuals' responses difficult.
Structured interview, questionnaires, and tests	Self-report instruments in which each participant is asked the same questions in the same way	Permits comparisons of participants' responses and efficient data collection. Researchers can specify answer alternatives that participants might not think of in an open-ended interview.	Does not yield the same depth of information as a clinical interview. Responses are still subject to inaccurate reporting.
<b>CLINICAL, OR CASE STUDY, METHOD</b>			
	A full picture of one individual's psychological functioning, obtained by combining interviews, observations, and test scores	Provides rich, descriptive insights into factors that affect development.	May be biased by researchers' theoretical preferences. Findings cannot be applied to individuals other than the participant.
<b>ETHNOGRAPHY</b>			
	Participant observation of a culture or distinct social group. By making extensive field notes, the researcher tries to capture the culture's unique values and social processes	Provides a more complete description than can be derived from a single observational visit, interview, or questionnaire.	May be biased by researchers' values and theoretical preferences. Findings cannot be applied to individuals and settings other than the ones studied.

© LAURA DWIGHT PHOTOGRAPHY

In naturalistic observation, the researcher goes into the field and records the behavior of interest. Here, a research assistant observes children at preschool. She may be focusing on their playmate choices, cooperation, helpfulness, or conflicts.

laboratory situation that evokes the behavior of interest so that every participant has equal opportunity to display the response. In one such study, 2-year-olds' emotional reactions to harm that they thought they had caused were observed by asking each of them to take care of a rag doll that had been modified so its leg would fall off when the child picked it up. To make the child feel at fault, once the leg detached, an adult "talked for" the doll, saying, "Ow!" Researchers recorded children's facial expressions of sadness and concern for the injured doll, efforts to help the doll, and body tension—responses that indicated worry, remorse, and a desire to make amends. In addition, mothers were asked to engage in brief conversations about emotions with their children (Garner, 2003). Toddlers whose mothers more often explained the causes and consequences of emotion were more likely to express concern for the injured doll.

The procedures used to collect systematic observations vary, depending on the research problem posed. Sometimes investigators choose to describe the entire stream of behavior—everything said and done over a certain time period. In one study, researchers wanted to find out whether maternal sensitivity in infancy and early childhood contributes to readiness for formal schooling at age 6 (Hirsh-Pasek & Burchinal, 2006). Between ages 6 months and 4½ years, the investigators periodically videotaped mother-child play sessions. Then they rated each session for many behaviors—maternal positive emotion, support, stimulating play, and respect for the child's autonomy. These ingredients of sensitivity did predict better language and academic progress when the children reached kindergarten.

Researchers have devised ingenious ways of observing difficult-to-capture behaviors. For example, to record instances

of bullying, a group of investigators set up video cameras overlooking a classroom and a playground and had fourth to sixth graders wear small, remote microphones and pocket-sized transmitters (Craig, Pepler, & Atlas, 2000). Results revealed that bullying occurred often—at rates of 2.4 episodes per hour in the classroom and 4.5 episodes per hour on the playground. Yet only 15 to 18 percent of the time did teachers take steps to stop the harassment.

Systematic observation provides invaluable information on how children and adults actually behave, but it tells us little about the reasoning behind their responses. For this kind of information, researchers must turn to self-report techniques.

**Self-Reports.** Self-reports ask research participants to provide information on their perceptions, thoughts, abilities, feelings, attitudes, beliefs, and past experiences. They range from relatively unstructured interviews to highly structured interviews, questionnaires, and tests.

In a **clinical interview**, researchers use a flexible, conversational style to probe for the participant's point of view. In the following example, Piaget questioned a 5-year-old child about his understanding of dreams:

*Where does the dream come from?—I think you sleep so well that you dream.—Does it come from us or from outside?—From outside.—When you are in bed and you dream, where is the dream?—In my bed, under the blanket. I don't really know. If it was in my stomach, the bones would be in the way and I shouldn't see it.—Is the dream there when you sleep?—Yes, it is in the bed beside me. (Piaget, 1926/1930, pp. 97–98)*

Although a researcher conducting clinical interviews with more than one participant would typically ask the same first question to establish a common task, individualized prompts are used to provide a fuller picture of each person's reasoning.

The clinical interview has two major strengths. First, it permits people to display their thoughts in terms that are as close as possible to the way they think in everyday life. Second, the clinical interview can provide a large amount of information in a fairly brief period (Sharp et al., 2013). For example, in an hour-long session, we can obtain a wide range of information on child rearing from a parent or on life circumstances from an older adult—much more than we could capture by observing for the same amount of time.

A major limitation of the clinical interview has to do with the accuracy with which people report their thoughts, feelings, and experiences. Some participants, wishing to please the interviewer, may make up answers that do not represent their actual thinking. When asked about past events, some may have trouble recalling exactly what happened. And because the clinical interview depends on verbal ability and expressiveness, it may underestimate the capacities of individuals who have difficulty putting their thoughts into words.

The clinical interview has also been criticized because of its flexibility. When questions are phrased differently for each participant, responses may reflect the manner of interviewing rather than real differences in the way people think about a topic.

**Structured interviews** (including tests and questionnaires), in which each participant is asked the same set of questions in the same way, eliminate this problem. These instruments are also much more efficient. Answers are briefer, and researchers can obtain written responses from an entire group at the same time. Furthermore, by listing answer alternatives, researchers can specify the activities and behaviors of interest—ones that participants might not think of in an open-ended clinical interview. For example, when a sample of parents was asked what they considered “the most important thing for children to prepare them for life,” 62 percent checked “to think for themselves” when this choice appeared on a list. Yet only 5 percent thought of this during a clinical interview (Schwarz, 2008).

Nevertheless, structured interviews do not yield the same depth of information as a clinical interview. And they can still be affected by the problem of inaccurate reporting.

**The Clinical, or Case Study, Method.** An outgrowth of psychoanalytic theory, the **clinical, or case study, method** brings together a wide range of information on one person, including interviews, observations, and test scores. The aim is to obtain as complete a picture as possible of that individual’s psychological functioning and the experiences that led up to it.

The clinical method is well-suited to studying the development of certain types of individuals who are few in number but vary widely in characteristics. For example, the method has been used to find out what contributes to the accomplishments of *prodigies*—extremely gifted children who attain adult competence in a field before age 10 (Moran & Gardner, 2006).

In one investigation, researchers conducted case studies of eight child prodigies nationally recognized for talents in such areas as art, music, and mathematics (Ruthsatz & Urbach, 2012). One child began playing the violin at 28 months, had won

regional competitions as a 5-year-old, and by age 7 had performed as a soloist at New York’s Carnegie Hall and Lincoln Center. Another child started reading as an infant, took college-level classes beginning at age 8, and published a paper in a mathematics journal at 13. Across the eight cases, the investigators noticed interesting patterns, including above-average intelligence and exceptionally high scores on tests of memory and attention to detail. Notably, several prodigies had relatives with autism, a condition that also involves intense attention to detail. The researchers concluded that although child prodigies generally do not display the cognitive and social deficits of autism, the two groups may share an underlying genetic trait that affects the functioning of certain brain regions, heightening perception and attention.

The clinical method yields richly detailed case narratives that offer valuable insights into the many factors influencing development. Nevertheless, like all other methods, it has drawbacks. Because information often is collected unsystematically and subjectively, researchers’ theoretical preferences may bias their observations and interpretations. In addition, investigators cannot assume that their conclusions apply, or generalize, to anyone other than the person studied (Stanovich, 2013). Even when patterns emerge across cases, it is wise to confirm these with other research strategies.

**Methods for Studying Culture.** To study the impact of culture, researchers adjust the methods just considered or tap procedures specially devised for cross-cultural and multicultural research. Which approach investigators choose depends on their research goals.

Sometimes researchers are interested in characteristics that are believed to be universal but that vary in degree from one society to the next: Are parents warmer or more directive in some cultures than others? How strong are gender stereotypes in different nations? In each instance, several cultural groups will be compared, and all participants must be questioned or observed in the same way. Therefore, researchers draw on the observational and self-report procedures we have already considered, adapting them through translation so they can be understood in each cultural context. For example, to study cultural variation in parenting practices, the same questionnaire, asking for ratings on such items as “I often start a conversation with my parents about what happens in school” or “My parents can tell when I’m upset about something,” is given to all participants (Qin & Pomerantz, 2013). Still, investigators must be mindful of cultural differences in familiarity with being observed and with responding to self-report instruments, which may bias their findings (van de Vijver, 2011).

At other times, researchers want to uncover the *cultural meanings* of children’s and adults’ behaviors by becoming as familiar as possible with their way of life. To achieve this goal, investigators rely on a method borrowed from the field of anthropology—**ethnography**. Like the clinical method, ethnographic research is a descriptive, qualitative technique. But instead of aiming to understand a single individual, it is directed toward understanding a culture or a distinct social group through

© LAURA DWIGHT PHOTOGRAPHY

Using the clinical, or case study, method, this researcher interacts with a 3-year-old during a home visit. Interviews and observations will contribute to an in-depth picture of this child’s psychological functioning.

A Western researcher works with Zinacantec Mayan children in Chiapas, Mexico, using the ethnographic method to gather information about how they learn through everyday activities.

*participant observation.* Typically, the researcher spends months, and sometimes years, in the cultural community, participating in its daily life. Extensive field notes are gathered, consisting of a mix of observations, self-reports from members of the culture, and careful interpretations by the investigator (Case, Todd, & Kral, 2014). Later, these notes are put together into a description of the community that tries to capture its unique values and social processes.

The ethnographic method assumes that entering into close contact with a social group will allow researchers to understand the beliefs and behaviors of its members in a way that is not possible with an observational visit, interview, or questionnaire. Some ethnographies take in many aspects of experience, as one researcher did in describing what it is like to grow up in a small American town. Others focus on one or a few settings and issues—for example, youth resilience in an economically disadvantaged Alaskan-Native community or African-Caribbean adults' reactions to a diagnosis of high blood pressure, signaling elevated risk for heart disease (Higginbottom, 2006; Peshkin, 1997; Rasmus, Allen, & Ford, 2014). Notice how such ethnographic evidence is vital for designing effective interventions. Researchers may supplement traditional self-report and observational methods with ethnography if they suspect that unique meanings underlie cultural differences, as the Cultural Influences box on page 32 reveals.

Ethnographers strive to minimize their influence on the culture they are studying by becoming part of it. Nevertheless, as with clinical research, investigators' cultural values and theoretical commitments sometimes lead them to observe selectively or misinterpret what they see. Finally, the findings of ethnographic studies cannot be assumed to generalize beyond the people and settings in which the research was conducted.

## Ask yourself

**CONNECT** What strengths and limitations do the clinical, or case study, method and ethnography have in common?

**APPLY** A researcher wants to study the thoughts and feelings of parents on active duty in the military and those of their school-age and adolescent children. Which method should she use? Why?

**REFLECT** Reread the description of nonnormative influences on page 10, and cite an example from your own life. Which method would be best suited to studying the impact of such a nonnormative event on development?

## General Research Designs

In deciding on a research design, investigators choose a way of setting up a study that permits them to test their hypotheses with the greatest certainty possible. Two main types of designs are used in all research on human behavior: *correlational* and *experimental*.

**Correlational Design.** In a **correlational design**, researchers gather information on individuals, generally in natural life circumstances, without altering their experiences. Then they look at relationships between participants' characteristics and their behavior or development. Suppose we want to answer such questions as, Do parents' styles of interacting with their children have any bearing on children's intelligence? Does the arrival of a baby influence a couple's marital satisfaction? Does death of a spouse in late adulthood affect the surviving partner's physical health and psychological well-being? In these and many other instances, the conditions of interest are difficult or impossible to arrange and control and must be studied as they currently exist.

BRENT WINEBENNER/GETTY IMAGES

Retirees enjoy socializing on the riverbank in the town of Split, Croatia. How do older adults' friendships affect their well-being? A correlational design can be used to answer this question, but it does not permit researchers to determine the precise cause of their findings.

## Cultural Influences

### Immigrant Youths: Adapting to a New Land

Over the past several decades, increasing numbers of immigrants have come to North America, fleeing war and persecution in their homelands or seeking better life chances. Today, nearly one-fourth of U.S. children and adolescents have foreign-born parents, mostly originating from Latin America, the Caribbean, Asia, and Africa. Although some move with their parents, more than 80 percent of young people from immigrant families are U.S.-born citizens (Hernandez, Denton, & Blanchard, 2011; Hernandez et al., 2012).

How well are these youths—now the fastest-growing sector of the U.S. youth population—adapting to their new country? To find out, researchers use multiple research methods: academic testing, questionnaires assessing psychological adjustment, and in-depth ethnographies.

#### Academic Achievement and Adjustment

Although educators and laypeople often assume that the transition to a new country has a negative impact on psychological well-being, many children of immigrant parents adapt amazingly well. Students who are foreign-born (immigrated with their parents) or first-generation (American-born, with immigrant parents) often achieve in school as well as or better than students of native-born parents (Hao & Woo, 2012; Hernandez, Denton, & Blanchard, 2011). And compared with their agetates, adolescents from immigrant families are less likely to commit delinquent and violent acts, use drugs and alcohol, have early sex, miss school because of illness, or suffer from obesity. Furthermore, they report just as favorable, and at times higher, self-esteem as do young people with native-born parents (Saucier et al., 2002; Supple & Small, 2006).

These outcomes are strongest for Chinese, Filipino, Japanese, Korean, and East Indian youths, less dramatic for other ethnicities (Fuligni, 2004; Louie, 2001; Portes & Rumbaut, 2005). Variation in adjustment is greater among Mexican, Central American, and Southeast

Asian (Hmong, Cambodian, Laotian, Thai, and Vietnamese) young people, who show elevated rates of school failure and dropout, delinquency, teenage parenthood, and drug use (García Coll & Marks, 2009; Pong & Landale, 2012). Disparities in parental economic resources, education, English-language proficiency, and support of children contribute to these trends.

Still, many first- and second-generation youths whose parents face considerable financial hardship and who speak little English are successful (Hao & Woo, 2012). Factors other than income are responsible—notably, family values and strong ethnic-community ties.

#### Family and Ethnic-Community Influences

Ethnographies reveal that immigrant parents view education as the surest way to improve life chances (García Coll & Marks, 2009). They typically emphasize trying hard, reminding their children that, because educational opportunities were not available in their native countries, they themselves are often limited to menial jobs.

Adolescents from these families internalize parental valuing of education more strongly than do agetates with native-born parents (Fuligni, 2004; Su & Costigan, 2008). Because minority ethnicities usually stress allegiance to family and community over individual goals, immigrant young people feel a strong sense of obligation to their parents. They view school success as an important way of repaying their parents for the hardships they have endured (Bacallao & Smokowski, 2007; van Geel & Vedder, 2011). Both family relationships and school achievement protect these youths from risky behaviors (see the Biology and Environment box on pages 10–11).

Immigrant parents of successful youths typically develop close ties to an ethnic community, which exerts additional control

These Tibetan-American children march in an international immigrants parade in New York City. Cultural values that engender allegiance to family and community promote high achievement and protect many immigrant youths from involvement in risky behaviors.

through a high consensus on values and constant monitoring of young people's activities. The following comments capture the power of these family and community forces:

*A 16-year-old girl from Central America describes the supportive adults in her neighborhood: They ask me if I need anything for school. If we go to a store and I see a notebook, they ask me if I want it. They give me advice, tell me that I should be careful of the friends I choose. They also tell me to stay in school to get prepared. They tell me I am smart. They give me encouragement. (Suárez-Orozco, Pimental, & Martin, 2009, p. 733)*

*A teenage boy from Mexico discusses the importance of family in his culture: A really big part of the Hispanic population [is] being close to family, and the family being a priority all the time. I hate people who say, "Why do you want to go to a party where your family's at? Don't you want to get away from them?" You know, I don't really get tired of them. I've always been really close to them. That connection to my parents, that trust that you can talk to them, that makes me Mexican. (Bacallao & Smokowski, 2007, p. 62)*

The experiences of well-adjusted immigrant youths are not problem-free. Many encounter racial and ethnic prejudices and experience tensions between family values and the new culture—challenges we will take up in Chapter 12. In the long term, however, family and community cohesion, supervision, and high expectations promote favorable outcomes.

Correlational studies have one major limitation: We cannot infer cause and effect. For example, if we were to find that parental interaction is related to children's intelligence, we would not know whether parents' behavior actually *causes* intellectual differences among children. In fact, the opposite is possible. The behaviors of highly intelligent children may be so attractive that they cause parents to interact more favorably. Or a third variable that we did not even consider, such as the amount of noise and distraction in the home, may cause changes in both parental interaction and children's intelligence.

In correlational studies and in other types of research designs, investigators often examine relationships by using a **correlation coefficient**—a number that describes how two measures, or variables, are associated with each other. We will encounter the correlation coefficient in discussing research findings throughout this book, so let's look at what it is and how it is interpreted. A correlation coefficient can range in value from +1.00 to -1.00. The *magnitude*, or *size*, of the number shows the *strength of the relationship*. A zero correlation indicates no relationship; the closer the value is to +1.00 or -1.00, the stronger the relationship (see Figure 1.6). For instance, a correlation of -.78 is high, -.52 is moderate, and -.18 is low. Note, however, that correlations of +.52 and -.52 are equally strong. The *sign of the number* (+ or -) refers to the *direction of the relationship*. A positive sign (+) means that as one variable *increases*, the other also *increases*. A negative sign (-) indicates that as one variable *increases*, the other *decreases*.

Let's look at some examples of how a correlation coefficient works. One researcher reported a +.55 correlation between a measure of maternal language stimulation and the size of 2-year-olds' vocabularies (Hoff, 2003). This is a moderate correlation, which indicates that toddlers whose mothers spoke more to them tended to be advanced in language development. In two other studies, child-rearing practices were related to tod-

dlers' compliance in consistent ways. First, maternal warmth and sensitivity during play correlated positively with 2-year-olds' willingness to comply with their mother's directive to clean up toys, at +.34 (Feldman & Klein, 2003). Second, the extent to which mothers spoke harshly, interrupted, and controlled their 4-year-olds' play correlated negatively with children's compliance, at -.31 for boys and -.42 for girls (Smith et al., 2004).

All these investigations found a relationship between parenting and young children's behavior. Are you tempted to conclude that the maternal behaviors influenced children's responses? Although the researchers in these studies suspected this was so, they could not be sure of cause and effect. Can you think of other possible explanations? Finding a relationship in a correlational study suggests that tracking down its cause—using a more powerful experimental strategy, if possible—would be worthwhile.

**Experimental Design** An **experimental design** permits inferences about cause and effect because researchers use an evenhanded procedure to assign people to two or more treatment conditions. In an experiment, the events and behaviors of interest are divided into two types: independent and dependent variables. The **independent variable** is the one the investigator expects to cause changes in another variable. The **dependent variable** is the one the investigator expects to be influenced by the independent variable. Cause-and-effect relationships can be detected because the researcher directly *controls* or *manipulates* changes in the independent variable by exposing participants to the treatment conditions. Then the researcher compares their performance on measures of the dependent variable.

In one *laboratory experiment*, researchers explored the impact of adults' angry interactions on children's adjustment (El-Sheikh, Cummings, & Reiter, 1996). They hypothesized that the way angry encounters end (independent variable) affects children's emotional reactions (dependent variable). Four- and 5-year-olds were brought one at a time to a laboratory, accompanied by their mothers. One group was exposed to an *unresolved-anger treatment*, in which two adult actors entered the room and argued but did not work out their disagreements. The other group witnessed a *resolved-anger treatment*, in which the adults ended their disputes by apologizing and compromising. When witnessing a follow-up adult conflict, children in the *resolved-anger treatment* showed less distress, as measured by fewer anxious facial expressions, less freezing in place, and less seeking of closeness to their mothers. The experiment revealed that anger resolution can reduce the stressful impact of adult conflict on children.

In experimental studies, investigators must take special precautions to control for participants' characteristics that could reduce the accuracy of their findings. For example, in the study just described, if a greater number of children from homes high in parental conflict ended up in the unresolved-anger treatment, we could not tell what produced the results—the independent variable or the children's family backgrounds. To protect against this problem, researchers engage in **random assignment** of participants to treatment conditions. By using an unbiased procedure, such as drawing numbers out of a hat or flipping a coin,

**FIGURE 1.6** The meaning of correlation coefficients. The magnitude of the number indicates the *strength* of the relationship. The sign of the number (+ or -) indicates the *direction* of the relationship.

investigators increase the chances that participants' characteristics will be equally distributed across treatment groups.

**Modified Experimental Designs: Field and Natural Experiments.** Most experiments are conducted in laboratories, where researchers can achieve the maximum possible control over treatment conditions. But, as we have already indicated, findings obtained in laboratories may not always apply to everyday situations. In *field experiments*, investigators capitalize on opportunities to assign participants randomly to treatment conditions in natural settings. In the experiment just described, we can conclude that the emotional climate established by adults affects children's behavior in the laboratory. But does it also do so in daily life?

Another study helps answer this question. Ethnically diverse, poverty-stricken families with a 2-year-old child were scheduled for a home visit, during which researchers assessed family functioning and child problem behaviors by asking parents to respond to questionnaires and videotaping parent-child interaction. Then the families were randomly assigned to either a brief intervention condition, called the Family Check-Up, or a no-intervention control group. The intervention consisted of three home-based sessions in which a consultant gave parents feedback about their child-rearing practices and their child's adjustment, explored

parents' willingness to improve, identified community services appropriate to each family's needs, and offered follow-up sessions on parenting practices and other concerns (Brennan et al., 2013; Dishion et al., 2008). Findings showed that families assigned to the Family Check-Up (but not controls) gained in positive parenting, which predicted a reduction in child problem behaviors and higher academic achievement when the children reached school age.

Often researchers cannot randomly assign participants and manipulate conditions in the real world. Sometimes they can compromise by conducting *natural*, or *quasi*-, *experiments*, comparing treatments that already exist, such as different family environments, schools, workplaces, or retirement villages. These studies differ from correlational research only in that groups of participants are carefully chosen to ensure that their characteristics are as much alike as possible. In this way, investigators do their best to rule out alternative explanations for their treatment effects. But despite these efforts, natural experiments cannot achieve the precision and rigor of true experimental research.

To help you compare correlational and experimental designs, Table 1.6 summarizes their strengths and limitations. It also includes an overview of designs for studying development, to which we turn next.

**TABLE 1.6**  
**Strengths and Limitations of Research Designs**

DESIGN	DESCRIPTION	STRENGTHS	LIMITATIONS
<b>GENERAL</b>			
Correlational	The investigator obtains information on participants without altering their experiences.	Permits study of relationships between variables.	Does not permit inferences about cause-and-effect relationships.
Experimental	Through random assignment of participants to treatment conditions, the investigator manipulates an independent variable and examines its effect on a dependent variable. Can be conducted in the laboratory or the natural environment.	Permits inferences about cause-and-effect relationships.	When conducted in the laboratory, findings may not generalize to the real world. In <i>field experiments</i> , control over the treatment is usually weaker than in the laboratory. In <i>natural</i> , or <i>quasi</i> -, <i>experiments</i> , lack of random assignment substantially reduces the precision of research.
<b>DEVELOPMENTAL</b>			
Longitudinal	The investigator studies the same group of participants repeatedly at different ages.	Permits study of common patterns and individual differences in development and relationships between early and later events and behaviors.	Age-related changes may be distorted because of participant dropout, practice effects, and cohort effects.
Cross-sectional	The investigator studies groups of participants differing in age at the same point in time.	More efficient than the longitudinal design. Not plagued by such problems as participant dropout and practice effects.	Does not permit study of individual developmental trends. Age differences may be distorted because of cohort effects.
Sequential	The investigator conducts several similar cross-sectional or longitudinal studies (called sequences). These might study participants over the same ages but in different years, or they might study participants over different ages but during the same years.	When the design includes longitudinal sequences, permits both longitudinal and cross-sectional comparisons. Also reveals cohort effects. Permits tracking of age-related changes more efficiently than the longitudinal design.	May have the same problems as longitudinal and cross-sectional strategies, but the design itself helps identify difficulties.

## Designs for Studying Development

Scientists interested in human development require information about the way research participants change over time. To answer questions about development, they must extend correlational and experimental approaches to include measurements at different ages. Longitudinal and cross-sectional designs are special *developmental research strategies*. In each, age comparisons form the basis of the research plan.

**The Longitudinal Design.** In a **longitudinal design**, participants are studied repeatedly, and changes are noted as they get older. The time spanned may be relatively short (a few months to several years) or very long (a decade or even a lifetime). The longitudinal approach has two major strengths. First, because it tracks the performance of each person over time, researchers can identify common patterns as well as individual differences in development. Second, longitudinal studies permit investigators to examine relationships between early and later events and behaviors. Let's illustrate these ideas.

A group of researchers wondered whether children who display extreme personality styles—either angry and explosive or shy and withdrawn—retain the same dispositions when they become adults. In addition, the researchers wanted to know what kinds of experiences promote stability or change in personality and what consequences explosiveness and shyness have for long-term adjustment. To answer these questions, the researchers delved into the archives of the Guidance Study, a well-known longitudinal investigation initiated in 1928 at the University of California, Berkeley, that continued for several decades (Caspi, Elder, & Bem, 1987, 1988).

Results revealed that the two personality styles were moderately stable. Between ages 8 and 30, a good number of individuals remained the same, whereas others changed substantially. When stability did occur, it appeared to be due to a “snowballing effect,” in which children evoked responses from adults and peers that acted to maintain their dispositions. Explosive youngsters were likely to be treated with anger, whereas shy children were apt to be ignored. As a result, the two types of children came to view their social worlds differently. Explosive children regarded others as hostile; shy children regarded them as unfriendly (Caspi & Roberts, 2001). Together, these factors led explosive children to sustain or increase their unruliness and shy children to continue to withdraw.

Persistence of extreme personality styles affected many areas of adult adjustment. For men, the results of early explosiveness were most apparent in their work lives, in the form of conflicts with supervisors, frequent job changes, and unemployment. Since few women in this sample of an earlier generation worked after marriage, their family lives were most affected. Explosive girls grew up to be hotheaded wives and mothers who were especially prone to divorce. Sex differences in the long-term consequences of shyness were even greater. Men who had been withdrawn in childhood were delayed in marrying, becoming fathers, and developing stable careers. However, because a

withdrawn, unassertive style was socially acceptable for females in the mid-twentieth century, women with shy personalities showed no special adjustment problems.

### Problems in Conducting Longitudinal Research.

Despite their strengths, longitudinal investigations pose a number of problems. For example, participants may move away or drop out of the research for other reasons. This biases the sample so that it no longer represents the population to whom researchers would like to generalize their findings. Also, from repeated study, people may become more aware of their own thoughts, feelings, and actions and revise them in ways that have little to do with age-related change. In addition, they may become “test-wise.” Their performance may improve as a result of *practice effects*—better test-taking skills and increased familiarity with the test—not because of factors commonly associated with development.

The most widely discussed threat to the accuracy of longitudinal findings is **cohort effects** (see pages 9–10): Individuals born in the same time period are influenced by a particular set of historical and cultural conditions. Results based on one cohort may not apply to people developing at other times. For example, consider the results on female shyness described in the preceding section, which were gathered in the 1950s. Today's shy adolescent girls and young women tend to be poorly adjusted—a difference that may be due to changes in gender roles in Western societies. Shy adults, whether male or female, feel more anxious and depressed, have fewer social supports, are delayed in forming romantic partnerships, and do less well in educational and

SPENCER PLATT/GETTY IMAGES

These refugees being helped ashore in Greece are among millions of Syrians who have been displaced by or have fled their country's civil war. Their lives have been dramatically altered by their wartime and migration experiences—a cohort effect deemed the largest humanitarian crisis of contemporary times.

career attainment than their age mates (Asendorpf, Denissen, & van Aken, 2008; Karevold et al., 2012; Mounts et al., 2006). Similarly, a longitudinal study of lifespan development would probably result in quite different findings if it were carried out in the second decade of the twenty-first century, around the time of World War II, or during the Great Depression of the 1930s.

Cohort effects don't just operate broadly on an entire generation. They also occur when specific experiences influence some groups of individuals but not others in the same generation. For example, children who witnessed the terrorist attacks of September 11, 2001 (either because they were near Ground Zero or because they saw injury and death on TV), or who lost a parent in the disaster, were far more likely than other children to display persistent emotional problems, including intense fear, anxiety, and depression (Mullett-Hume et al., 2008; Rosen & Cohen, 2010).

**The Cross-Sectional Design.** The length of time it takes for many behaviors to change, even in limited longitudinal studies, has led researchers to turn to a more efficient strategy for studying development. In the **cross-sectional design**, groups of people differing in age are studied at the same point in time. Because participants are measured only once, researchers need not be concerned about such difficulties as participant dropout or practice effects.

A study in which students in grades 3, 6, 9, and 12 filled out a questionnaire about their sibling relationships provides a good illustration (Buhrmester & Furman, 1990). Findings revealed that sibling interaction was characterized by greater equality and less power assertion with age. Also, feelings of sibling companionship declined in adolescence. The researchers thought that several factors contributed to these age differences. As later-born children become more competent and independent, they no longer need, and are probably less willing to accept, direction from older siblings. And as adolescents move from psychological dependence on the family to greater involvement with peers, they may have less time and emotional need to invest in siblings. As we will see in Chapter 12, subsequent research has confirmed these intriguing ideas about the development of sibling relationships.

### Problems in Conducting Cross-Sectional Research.

Despite its convenience, cross-sectional research does not provide evidence about development at the level at which it actually occurs: the individual. For example, in the cross-sectional study of sibling relationships just discussed, comparisons are limited to age-group averages. We cannot tell if important individual differences exist. Indeed, longitudinal findings reveal that adolescents vary considerably in the changing quality of their sibling relationships. Although many become more distant, others become more supportive and intimate, still others more rivalrous and antagonistic (Kim et al., 2006; McHale, Updegraff, & Whiteman, 2012).

Cross-sectional studies—especially those that cover a wide age span—have another problem. Like longitudinal research,

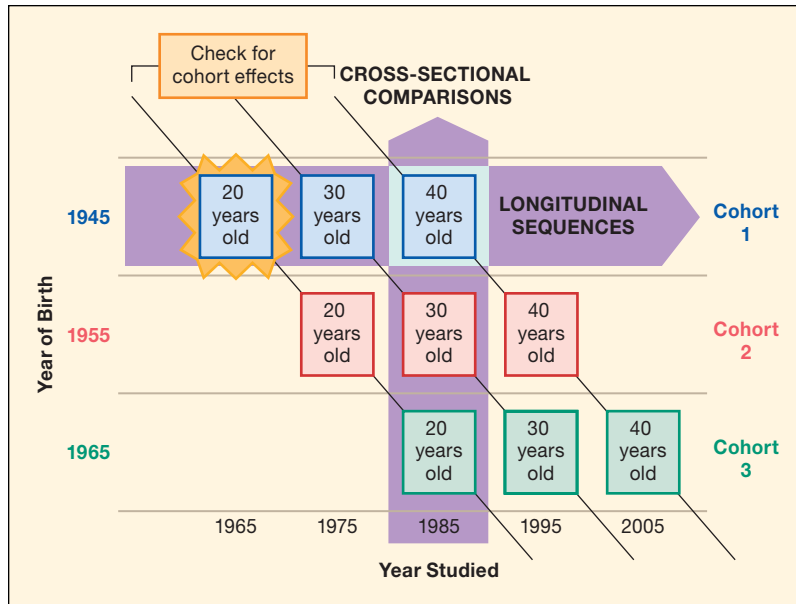

they can be threatened by cohort effects. For example, comparisons of 25-year-old cohorts, 50-year-old cohorts, and 75-year-old cohorts—groups born, reared, and educated in different years—may not really represent age-related changes (MacDonald & Stawski, 2016). Instead, they may reflect unique experiences associated with the historical period in which the age groups were growing up.

**Improving Developmental Designs.** Researchers have devised ways of building on the strengths and minimizing the weaknesses of longitudinal and cross-sectional approaches. Several modified developmental designs have resulted.

**Sequential Designs.** To overcome some of the limitations of traditional developmental designs, investigators sometimes use **sequential designs**, in which they conduct several similar cross-sectional or longitudinal studies (called *sequences*). The sequences might study participants over the same ages but in different years, or they might study participants over different ages but during the same years. Figure 1.7 illustrates the first of these options. As it also reveals, some sequential designs combine longitudinal and cross-sectional strategies, an approach that has two advantages:

- We can find out whether cohort effects are operating by comparing participants of the same age who were born in different years. In Figure 1.7, for example, we can compare the three longitudinal samples at ages 20, 30, and 40. If they do not differ, we can rule out cohort effects.
- We can make longitudinal and cross-sectional comparisons. If outcomes are similar in both, we can be especially confident about our findings.

In a study that used the design in Figure 1.7, researchers wanted to find out whether adult personality development progresses as Erikson's psychosocial theory predicts (Whitbourne et al., 1992). Questionnaires measuring Erikson's stages were given to three cohorts of 20-year-olds, each born a decade apart. The cohorts were reassessed at 10-year intervals. Consistent with Erikson's theory, longitudinal and cross-sectional gains in identity and intimacy occurred between ages 20 and 30 for all three cohorts, and sense of identity and intimacy in early adulthood predicted psychological well-being at midlife. But a powerful cohort effect emerged for consolidation of a sense of industry: At age 20, Cohort 1 scored substantially below Cohorts 2 and 3. Look at Figure 1.7 again and notice that members of Cohort 1 reached age 20 in the mid-1960s. As college students, they were part of an era of political protest that reflected disenchantment with the work ethic. Once out of college, they caught up with the other cohorts in industry, perhaps as a result of experiencing the pressures of the work world. Followed up in 2001 at age 54, Cohort 1 showed a decline in focus on identity issues and a gain in ego integrity (Sneed, Whitbourne, & Culang, 2006; Sneed et al., 2012). These trends are expected to continue through late adulthood.

**FIGURE 1.7** Example of a sequential design. Three cohorts, born in 1945 (blue), 1955 (pink), and 1965 (green), are followed longitudinally from 20 to 40 years of age. The design permits the researcher to check for cohort effects by comparing people of the same age who were born in different years. In a study that used this design, the 20-year-olds in Cohort 1 differed substantially from the 20-year-olds in Cohorts 2 and 3, indicating powerful history-graded influences. This design also permits longitudinal and cross-sectional comparisons. Similar findings lend additional confidence in the results.

By uncovering cohort effects, sequential designs help explain diversity in development. Yet to date only a small number of sequential studies have been conducted.

**Combining Experimental and Developmental Designs.** Perhaps you noticed that all the examples of longitudinal and cross-sectional research we have considered permit only correlational, not causal, inferences. Yet causal information is desirable, both for testing theories and for finding ways to enhance development. Sometimes researchers can explore the causal link between experiences and development by experimentally manipulating the experiences. If, as a result, development improves, then we have strong evidence for a causal association. Today, research that combines an experimental strategy with either a longitudinal or a cross-sectional approach is becoming increasingly common.

## Ask yourself

**CONNECT** Review the study of the Family Check-Up, described on page 34. Explain how it combines an experimental with a developmental design. What are the independent and dependent variables? Is its developmental design longitudinal or cross-sectional?

**APPLY** A researcher compares older adults with chronic heart disease to those with no major health problems and finds that the first group scores lower on mental tests. Can the researcher conclude that heart disease causes a decline in intellectual functioning in late adulthood? Explain.

**REFLECT** Suppose a researcher asks you to enroll your baby in a 10-year longitudinal study. What factors would lead you to agree and to stay involved? Do your answers shed light on why longitudinal studies often have biased samples?

## Ethics in Lifespan Research

**1.11** What special ethical concerns arise in research on human development?

Research into human behavior creates ethical issues because, unfortunately, the quest for scientific knowledge can sometimes exploit people. For this reason, special guidelines for research have been developed by the federal government, by funding agencies, and by research-oriented associations, such as the American Psychological Association (2010) and the Society for Research in Child Development (2007). Table 1.7 on page 38 presents a summary of basic research rights drawn from these guidelines. After examining them, read about the following research situations, each of which poses a serious ethical dilemma. What precautions do you think should be taken in each instance?

- In a study of moral development, an investigator wants to assess children's ability to resist temptation by videotaping their behavior without their knowledge. She promises 7-year-olds a prize for solving difficult puzzles but tells them not to look at a classmate's correct solutions, which are deliberately placed at the back of the room. Informing children ahead of time that cheating is being studied or that their behavior is being monitored will destroy the purpose of the study.
- A researcher wants to study the impact of mild daily exercise on the physical and mental health of patients in nursing homes. He consults each resident's doctor to make sure that the exercise routine will not be harmful. But when he seeks the residents' consent, he finds that many do not comprehend the purpose of the research. And some appear to agree simply to relieve feelings of isolation and loneliness.

**TABLE 1.7**  
**Rights of Research Participants**

RESEARCH RIGHT	DESCRIPTION
Protection from harm	Participants have the right to be protected from physical or psychological harm in research. If in doubt about the harmful effects of research, investigators should seek the opinion of others. When harm seems possible, investigators should find other means for obtaining the desired information or abandon the research.
Informed consent	All participants, including children and older adults, have the right to have explained to them, in language appropriate to their level of understanding, all aspects of the research that may affect their willingness to participate. When children are participants, informed consent of parents as well as others who act on the child's behalf (such as school officials) should be obtained, preferably in writing, along with the child's written or verbal assent (agreement) for participation. Older adults who are cognitively impaired should be asked to appoint a surrogate decision maker. If they cannot do so, then someone should be named by an institutional review board (IRB) after careful consultation with relatives and professionals who know the person well. All participants have the right to discontinue participation in the research at any time.
Privacy	Participants have the right to concealment of their identity on all information collected in the course of research. They also have this right with respect to written reports and any informal discussions about the research.
Knowledge of results	Participants have the right to be informed of the results of research in language that is appropriate to their level of understanding.
Beneficial treatments	If experimental treatments believed to be beneficial are under investigation, participants in control groups have the right to alternative beneficial treatments (if available) or to the same treatment (if found to be effective) once the research is complete.

Sources: American Psychological Association, 2010; Society for Research in Child Development, 2007.

As these examples indicate, when children or older adults take part in research, the ethical concerns are especially complex. Immaturity makes it difficult or impossible for children to evaluate for themselves what participation in research will mean. And because mental impairment rises with very advanced age, some older adults cannot make voluntary and informed choices (Dubois et al., 2011; Society for Research in Child Development, 2007). The life circumstances of others make them unusually vulnerable to pressure for participation.

Virtually every organization that has devised ethical principles for research has concluded that conflicts arising in research situations do not have simple right-or-wrong answers. The ultimate responsibility for the ethical integrity of research lies with the investigator. But researchers are advised—and often required—to seek advice from others. Committees for this purpose exist in colleges, universities, and other institutions. These *institutional review boards (IRBs)* follow federal guidelines for the protection of human subjects, which balance the costs of the research to participants in terms of inconvenience and possible psychological or physical harm against the study's value for advancing knowledge and improving conditions of life. If any risks to the safety and welfare of participants outweigh the worth of the research, then preference is always given to the participants' interests.

The ethical principle of *informed consent* requires special interpretation when participants cannot fully appreciate the research goals and activities. Parental consent is meant to protect the safety of children, whose ability to decide is not yet mature. But as soon as children are old enough to appreciate the purpose of the research, and certainly by age 7, their own informed *assent*, or agreement, should be obtained in addition to parental

consent. Around this age, changes in children's thinking permit them to better understand basic scientific principles and the needs of others. Researchers should respect and enhance these new capacities by giving children a full explanation of research activities in language they can understand (Birbeck & Drummond, 2015). Extra care must be taken when telling children that the information they provide will be kept confidential and that they can end their participation at any time. Even adolescents may not understand, and sometimes do not believe, these promises (Bruzese & Fisher, 2003). In certain ethnic minority communities, where deference to authority and meeting the needs of a guest (the researcher) are highly valued, children and parents may be particularly likely to consent or assent when they would rather not do so (Fisher et al., 2002).

Most older adults require no more than the usual informed-consent procedures. Yet many investigators set upper age limits in studies relevant to late adulthood, thereby excluding the oldest adults (Bayer & Tadd, 2000). Older adults should not be stereotyped as incompetent to decide about their own participation or to engage in research activities. Nevertheless, extra measures must be taken to protect those who are cognitively impaired or who reside in settings for the chronically ill. Yet participation should not be automatically withheld because it can result in personal as well as scientific benefits. In these instances, potential participants should be asked to appoint a surrogate decision maker. If they cannot do so, then someone should be named by an IRB, after careful consultation with relatives and professionals who know the person well. As an added precaution, if the older adult is incapable of consenting and the risks of the research are more than minimal, the study should not be done unless it is likely to benefit the participant directly (Dubois et al., 2011).

PIERRE ANDRIEU/APP/GETTY IMAGES

Older adults should not be arbitrarily excluded from research. Most require only typical informed-consent procedures, and their participation brings both personal and scientific benefits. But for some, including those who reside in settings for the chronically ill, informed consent may necessitate the assistance of a surrogate decision maker.

Finally, all ethical guidelines advise that special precautions be taken in the use of deception and concealment, as occurs when researchers observe people from behind one-way mirrors, give them false feedback about their performance, or do not tell them the truth about the real purpose of the research. When these

procedures are used with adults, *debriefing*, in which the investigator provides a full account and justification of the activities, occurs after the research session is over. But young children often lack the cognitive skills to understand the reasons for deceptive procedures and, despite explanations, even older children may leave the research situation questioning the honesty of adults. Ethical standards permit deception if investigators satisfy IRBs that such practices are necessary. Nevertheless, because deception may have serious emotional consequences for some youngsters, many experts in research ethics believe that investigators should use it with children only if the risk of harm is minimal.

## Ask yourself

**CONNECT** Review the field experiment on the impact of the Family Check-Up on page 34. Why is it ethically important for the researchers to offer the intervention to the no-intervention control group after completion of the study? (*Hint:* Refer to Table 1.7 on page 38.)

**APPLY** As a researcher gathers observations of the activities of several older adults with cognitive impairments in a nursing home, one resident says, “Stop watching me!” How should the researcher respond, and why?

**REFLECT** What ethical safeguards do you consider vital in conducting research that requires deception of children?

## Summary / chapter 1

### A Scientific, Applied, and Interdisciplinary Field (p. 5)

#### 1.1 What is developmental science, and what factors stimulated expansion of the field?

- Developmental science is an interdisciplinary field devoted to understanding human constancy and change throughout the lifespan. Research on human development has been stimulated by both scientific curiosity and social pressures to improve people's lives.

### Basic Issues (p. 5)

#### 1.2 Identify three basic issues on which theories of human development take a stand.

- Each theory of human development takes a stand on three fundamental issues: (1) Is development a **continuous** process or a series of **discontinuous stages**? (2) Does one general course of development characterize all indi-

viduals, or do many possible courses exist, depending on the **contexts** in which they live? (3) Are genetic or environmental factors more important in influencing development (the **nature–nurture controversy**), and are individual differences stable or characterized by substantial **plasticity**?

© AURORA PHOTOS/ROBERT HARDING

### The Lifespan Perspective: A Balanced Point of View (p. 7)

#### 1.3 Describe the lifespan perspective on development.

- The **lifespan perspective** envisions human change from a developmental systems perspective. It assumes that development is lifelong, multidimensional (affected by biological, psychological, and social forces), multidirectional (a joint expression of growth and decline), and plastic (open to change through new experiences).
- According to the lifespan perspective, the life course is influenced by multiple, interacting forces: (1) **age-graded influences**, which are predictable in timing and duration; (2) **history-graded influences**, unique to a particular historical era; and (3) **nonnormative influences**, unique to one or a few individuals.

## Scientific Beginnings (p. 12)

### 1.4 Describe major early influences on the scientific study of development.

- Darwin's theory of evolution influenced important developmental theories and inspired scientific child study. In the early twentieth century, Hall and Gesell introduced the **normative approach**, which measured behaviors of large groups to yield descriptive facts about development.

THOMAS TOLSTRUP/GETTY IMAGES

- Binet and Simon constructed the first successful intelligence test, which sparked interest in individual differences in development and led to a heated controversy over nature versus nurture.

## Mid-Twentieth-Century Theories (p. 14)

### 1.5 What theories influenced human development research in the mid-twentieth century?

- In the 1930s and 1940s, psychiatrists and social workers turned to the **psychoanalytic perspective** for help in treating people's emotional problems. In Freud's **psychosexual theory**, the individual moves through five stages, during which three portions of the personality—id, ego, and superego—become integrated. Erikson's **psychosocial theory** expands Freud's theory, emphasizing the development of culturally relevant attitudes and skills and the lifespan nature of development.
- As the psychoanalytic perspective gained in prominence, **behaviorism** and **social learning theory** emerged, emphasizing the study of directly observable events—stimuli and responses—and the principles of conditioning and modeling. These approaches gave rise to **applied behavior analysis**, in which procedures of conditioning and modeling are used to eliminate undesirable behaviors and increase desirable responses.

- Piaget's **cognitive-developmental theory** emphasizes that children actively construct knowledge as they move through four stages, beginning with the baby's sensorimotor action patterns and ending with the abstract, systematic reasoning system of the adolescent and adult. Piaget's work has stimulated a wealth of research on children's thinking and encouraged educational programs emphasizing children's discovery learning.

## Recent Theoretical Perspectives (p. 19)

### 1.6 Describe recent theoretical perspectives on human development.

- **Information processing** views the mind as a complex symbol-manipulating system, much like a computer. Because this approach provides precise accounts of how children and adults tackle cognitive tasks, its findings have important implications for education.
- Researchers in **developmental cognitive neuroscience** study the relationship between changes in the brain and the development of cognitive processing and behavior patterns. More recently, investigators in **developmental social neuroscience** are examining relationships between changes in the brain and emotional and social development. Findings on experiences that affect brain development at various ages are contributing to interventions for enhancing cognitive and social functioning.

© LAURA DWIGHT PHOTOGRAPHY

- Three contemporary perspectives emphasize *contexts* for development. The first, **ethology** stresses the adaptive value of behavior and inspired the **sensitive period** concept. In **evolutionary developmental psychology**, which extends this emphasis, researchers seek to understand the adaptiveness of specieswide competencies as they change with age.

- The second perspective, Vygotsky's **sociocultural theory**, which focuses on how culture is transmitted from one generation to the next through social interaction, views cognitive development as a socially mediated process. Through cooperative dialogues with more expert members of society, children come to use language to guide their own thought and actions and acquire culturally relevant knowledge and skills.

© FLORESCO PRODUCTIONS/CORBIS

- The third perspective, **ecological systems theory**, views the individual as developing within a complex system of relationships affected by multiple, nested layers of the surrounding environment—**microsystem**, **mesosystem**, **exosystem**, and **macrosystem**. The **chronosystem** represents the dynamic, ever-changing nature of individuals and their experiences.

## Comparing and Evaluating Theories (p. 26)

### 1.7 Identify the stand taken by each major theory on the three basic issues of human development.

- Theories vary in their focus on different domains of development, in their view of how development occurs, and in their strengths and weaknesses. (For a full summary, see Table 1.4 on page 27.)

## Studying Development (p. 26)

### 1.8 Describe methods commonly used in research on human development.

- **Naturalistic observations**, gathered in everyday environments, permit researchers to see directly the everyday behaviors they hope to explain. **Structured observations**, which take place in laboratories, give every participant an equal opportunity to display the behaviors of interest.

- Self-report methods can be flexible and open-ended like the **clinical interview**, which permits participants to express their thoughts in ways similar to their thinking in everyday life. **Structured interviews**—including tests and questionnaires—are more efficient, permitting researchers to specify activities and behaviors that participants might not think of in an open-ended interview. Investigators use the **clinical, or case study, method** to obtain an in-depth understanding of a single individual.
- Researchers have adapted observational and self-report methods to permit direct comparisons of cultures. To uncover the cultural meanings of behavior, they rely on **ethnography**, engaging in participant observation.

© KEITH DANNEMILLER/ALAMY STOCK PHOTO

### 1.9 Distinguish between correlational and experimental research designs, noting the strengths and limitations of each.

- The **correlational design** examines relationships between variables without altering participants' experiences. The **correlation coefficient** is often used to measure the association between variables. Correlational studies do not permit inferences about cause and effect, but they can help identify relationships that are worth exploring with a more powerful experimental strategy.
- An **experimental design** permits inferences about cause and effect. Researchers manipulate an **independent variable** by exposing participants to two or more treatment conditions. Then they determine what effect this variable has on a **dependent variable**. **Random assignment** to treatment conditions reduces the chances that participants' characteristics will affect the accuracy of experimental findings.
- Field and natural, or quasi-, experiments compare treatments in natural environments. However, these approaches are less rigorous than laboratory experiments.

### 1.10 Describe designs for studying development, noting the strengths and limitations of each.

- In the **longitudinal design**, participants are studied repeatedly over time, revealing common patterns as well as individual differences in development and relationships between early and later events and behaviors. Longitudinal research poses several problems, including biased sampling, practice effects, and **cohort effects**—difficulty generalizing results from one cohort to people developing at other historical times.

- The **cross-sectional design**, in which groups of people differing in age are studied at the same point in time, offers a more efficient way to study development, but it is limited to comparisons of age-group averages and can be vulnerable to cohort effects.
- Sequential designs** compare participants of the same age born in different years to determine whether cohort effects are operating. When sequential designs combine longitudinal and cross-sectional strategies, researchers can see if outcomes are similar, for added confidence in their findings.
- Combining experimental and developmental designs permits researchers to examine causal influences on development.

## Ethics in Lifespan Research (p. 37)

### 1.11 What special ethical concerns arise in research on human development?

- Because the quest for scientific knowledge has the potential to exploit people, the ethical principle of informed consent requires special safeguards for children and for older adults who are cognitively impaired or who live in settings for the chronically ill.
- The use of deception in research with children is especially risky because it may undermine their basic faith in the honesty of adults.

## Important Terms and Concepts

age-graded influences (p. 9)  
 applied behavior analysis (p. 17)  
 behaviorism (p. 16)  
 chronosystem (p. 26)  
 clinical interview (p. 29)  
 clinical, or case study, method (p. 30)  
 cognitive-developmental theory (p. 17)  
 cohort effects (p. 35)

## Genetic and Environmental Foundations

Heredity and environment combine in intricate ways, making members of this multigenerational extended family both alike and different in physical characteristics and behavior.

# What's ahead in **chapter 2**

## Genetic Foundations

The Genetic Code • The Sex Cells • Boy or Girl? • Multiple Offspring • Patterns of Gene–Gene Interactions • Chromosomal Abnormalities

## Reproductive Choices

Genetic Counseling • Prenatal Diagnosis and Fetal Medicine • Adoption

■ **SOCIAL ISSUES: HEALTH** The Pros and Cons of Reproductive Technologies

## Environmental Contexts for Development

The Family • Socioeconomic Status and Family Functioning • Poverty • Affluence • Beyond the Family: Neighborhoods and Schools • The Cultural Context

■ **CULTURAL INFLUENCES** The African-American Extended Family

## Understanding the Relationship Between Heredity and Environment

The Question, “How Much?” • The Question, “How?”

■ **BIOLOGY AND ENVIRONMENT** The Tutsi Genocide and Epigenetic Transmission of Maternal Stress to Children

“It’s a girl!” announces the doctor, holding up the squalling newborn baby as her parents gaze with amazement at their miraculous creation.

“A girl! We’ve named her Sarah!” exclaims the proud father to eager relatives waiting for news of their new family member.

As we join these parents in thinking about how this wondrous being came into existence and imagining her future, we are struck by many questions. How could this baby, equipped with everything necessary for life outside the womb, have developed from the union of two tiny cells? What ensures that Sarah will, in due time, roll over, reach for objects, walk, talk, make friends, learn, imagine, and create—just like other typical children born before her? Why is she a girl and not a boy, dark-haired rather than blond, calm and cuddly instead of wiry and energetic? What difference will it make that Sarah is given a name and place in one family, community, nation, and culture rather than another?

To answer these questions, this chapter takes a close look at the foundations of development: heredity and environment. Because nature has prepared us for survival, all humans have features in common. Yet each of us is also unique. Take a moment to think about several of your friends, and jot down the most obvious physical and behavioral similarities between them and their parents. Did you find that one person shows combined features of both parents, another resembles just one parent, whereas a third is not like either parent? These directly observable characteristics are called **phenotypes**. They depend in part on the individual’s **genotype**—the complex blend of genetic information that determines our species and influences all our unique characteristics. Yet phenotypes are also affected by each person’s lifelong history of experiences.

We begin our discussion with a review of basic genetic principles that help explain similarities and differences among us in appearance and behavior. Then we turn to aspects of the environment that play powerful roles throughout the lifespan. As our discussion proceeds, some findings may surprise you. For example, many people believe that when children inherit unfavorable characteristics, little can be done to help them. Others are convinced that the damage done to a child by a harmful environment can easily be corrected. As we will see, neither of these assumptions is true. Rather, heredity and environment continuously collaborate, each modifying the power of the other to influence the course of development. In the final section of this chapter, we consider how nature and nurture work together. ●

## Genetic Foundations

- 2.1** What are genes, and how are they transmitted from one generation to the next?
- 2.2** Describe various patterns of gene–gene interaction.
- 2.3** Describe major chromosomal abnormalities, and explain how they occur.

Within each of the trillions of cells in the human body (except red blood cells) is a control center, or *nucleus*, that contains rod-like structures called **chromosomes**, which store and transmit genetic information. Human chromosomes come in 23 matching pairs; an exception is the XY pair in males, which we will discuss shortly. Each member of a pair corresponds to the other in size, shape, and genetic functions. One chromosome is inherited from the mother and one from the father (see Figure 2.1).

### The Genetic Code

Chromosomes are made up of a chemical substance called **deoxyribonucleic acid**, or **DNA**. As Figure 2.2 shows, DNA is a long, double-stranded molecule that looks like a twisted ladder. Each rung of the ladder consists of a specific pair of chemical substances called *bases*, joined together between the two sides. It is this sequence of base pairs that provides genetic instructions. A **gene** is a segment of DNA along the length of the chromosome. Genes can be of different lengths—perhaps 100 to several thousand ladder rungs long. An estimated 21,000 **protein-coding genes**, which directly affect our body’s characteristics, lie along the human chromosomes. They send instructions for making a rich assortment of proteins to the *cytoplasm*, the area surrounding the cell nucleus. Proteins, which trigger chemical reactions throughout the body, are the biological foundation on which our characteristics are built. An additional 18,000 **regulator genes** modify the instructions given by

protein-coding genes, greatly complicating their genetic impact (Pennisi, 2012).

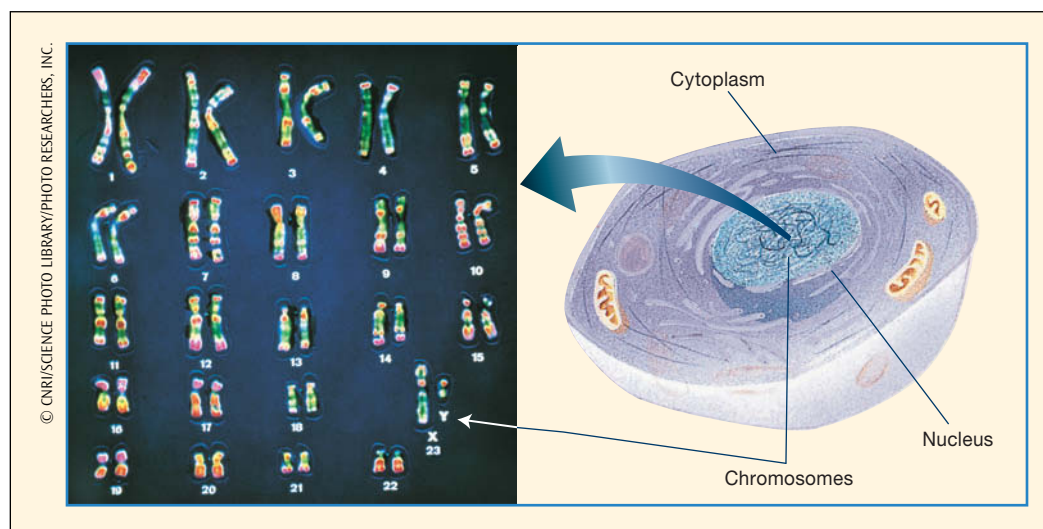

We share some of our genetic makeup with even the simplest organisms, such as bacteria and molds, and most of it with other mammals, especially primates. About 95 percent of chimpanzee and human DNA is identical. And the genetic variation from one human to the next is even less: Individuals around the world are about 99.6 percent genetically identical (Tishkoff & Kidd, 2004). But these straightforward comparisons are misleading. Many human DNA segments that appear like those of chimpanzees have undergone duplications and rearrangements with other segments. So in actuality, the species-specific genetic material responsible for the attributes that make us human, from our upright gait to our extraordinary language and cognitive capacities, is extensive (Preuss, 2012). Furthermore, it takes a change in only a single DNA base pair to influence human traits. And such tiny changes generally combine in unique ways across multiple genes, thereby amplifying variability within the human species.

How do humans, with far fewer genes than scientists once thought (only twice as many as the worm or fly), manage to develop into such complex beings? The answer lies in the proteins our genes make, which break up and reassemble in staggering variety—about 10 to 20 million altogether. Simpler species have far fewer proteins. Furthermore, the communication system between the cell nucleus and cytoplasm, which fine-tunes gene activity, is more intricate in humans than in simpler organisms. Finally, within the cell, a wide range of environmental factors modify gene expression. Recent evidence reveals that many such effects are unique to humans and influence brain development (Hernando-Herraez et al., 2013). So even at this microscopic level, biological events of profound developmental significance are the result of *both* genetic and nongenetic forces.

### The Sex Cells

New individuals are created when two special cells called **gametes**, or sex cells—the sperm and ovum—combine. A gamete contains

**FIGURE 2.1** A karyotype, or photograph, of human chromosomes. The 46 chromosomes shown on the left were isolated from a human cell, stained, greatly magnified, and arranged in pairs according to decreasing size of the upper “arm” of each chromosome. The twenty-third pair, XY, reveals that the cell donor is a male. In a female, this pair would be XX.

**FIGURE 2.2 DNA's ladderlike structure.** A gene is a segment of DNA along the length of the chromosome, varying from perhaps 100 to several thousand ladder rungs long. The pairings of bases across the rungs of the ladder are very specific: Adenine (A) always appears with thymine (T), and cytosine (C) always appears with guanine (G).

only 23 chromosomes, half as many as a regular body cell. Gametes are formed through a cell division process called **meiosis**, which halves the number of chromosomes normally present in body cells. When sperm and ovum unite at conception, the resulting cell, called a **zygote**, will again have 46 chromosomes.

In meiosis, the chromosomes pair up and exchange segments, so that genes from one are replaced by genes from another. Then chance determines which member of each pair will gather with others and end up in the same gamete. These events make the likelihood extremely low—about 1 in 700 trillion—that non-twin siblings will be genetically identical (Gould & Keeton, 1996). The genetic variability produced by meiosis is adaptive: It increases the chances that at least some members of a species will cope with ever-changing environments and will survive.

In the male, four sperm are produced when meiosis is complete. Also, the cells from which sperm arise are produced continuously throughout life. For this reason, a healthy man can father a child at any age after sexual maturity. In the female, meiosis results in just one ovum. In addition, the female is born with a bank of ova already present in her ovaries, though recent findings suggest that new ova may arise from ovarian stem cells later on (Virant-Klun, 2015). Still, there are plenty of female sex cells. About 1 to 2 million are present at birth, 40,000 remain at adolescence, and approximately 350 to 450 will mature during a woman's childbearing years (Moore, Persaud, & Torchia, 2016b).

## Boy or Girl?

Return to Figure 2.1 and note that 22 of the 23 pairs of chromosomes are matching pairs, called **autosomes** (meaning *not* sex chromosomes). The twenty-third pair consists of **sex chromosomes**. In females, this pair is called XX; in males, it is called XY. The X is a relatively long chromosome, whereas the Y is short and carries little genetic material. When gametes form in males, the X and Y chromosomes separate into different sperm cells. The gametes that form in females all carry an X chromosome. Therefore, the sex of the new organism is determined by whether an X-bearing or a Y-bearing sperm fertilizes the ovum.

## Multiple Offspring

Ruth and Peter, a couple I know well, tried for several years to have a child, without success. When Ruth reached age 33, her doctor prescribed a fertility drug, and twins—Jeannie and Jason—were born. Jeannie and Jason are **fraternal**, or **dizygotic**, **twins**, the most common type of multiple offspring, resulting from the release and fertilization of two ova. Genetically, they are no more alike than ordinary siblings. Table 2.1 summarizes genetic and environmental factors that increase the chances of giving birth to fraternal twins. Older maternal age, fertility drugs, and in vitro fertilization are major causes of the dramatic rise in fraternal twinning and other multiple births in industrialized nations over the past several decades. Currently, fraternal twins account for 1 in about every 33 births in the United States (Martin et al., 2015).

**TABLE 2.1**  
**Maternal Factors Linked to Fraternal Twinning**

FACTOR	DESCRIPTION
Ethnicity	Occurs in 6 to 9 per 1,000 births among Asians and Hispanics, 9 to 12 per 1,000 births among white Europeans, and 11 to 18 or more per 1,000 births among black Africans <sup>a</sup>
Family history of twinning	Occurs more often among women whose mothers and sisters gave birth to fraternal twins, suggesting a hereditary influence through the female line
Age	Rises with maternal age, peaking between 35 and 39 years, and then rapidly falls
Nutrition	Occurs less often among women with poor diets; occurs more often among women who are tall and overweight or of normal weight as opposed to slight body build
Number of births	Is more likely with each additional birth
Fertility drugs and in vitro fertilization	Is more likely with fertility hormones and in vitro fertilization (see page 52), which also increase the chances of bearing higher-order multiples

<sup>a</sup>Worldwide rates, not including multiple births resulting from use of fertility drugs.

These identical, or monozygotic, twins were created when a duplicating zygote separated into two clusters of cells, which developed into two individuals with the same genetic makeup.

Twins can be created in another way. Sometimes a zygote that has started to duplicate separates into two clusters of cells that develop into two individuals. These are called **identical, or monozygotic, twins** because they have the same genetic makeup. The frequency of identical twins is the same around the world—about 1 in every 350 to 400 births (Kulkarni et al., 2013). Animal research has uncovered a variety of environmental influences that prompt this type of twinning, including temperature changes, variation in oxygen levels, and late fertilization of the ovum (Lashley, 2007). In a minority of cases, identical twinning runs in families, but this occurs so rarely that it is likely due to chance rather than heredity.

During their early years, children of single births often are healthier and develop more rapidly than twins. Jeannie and Jason, like most twins, were born early—three weeks before Ruth’s due date. And, like other premature infants—as you will see in Chapter 3—they required special care after birth. When the twins came home from the hospital, Ruth and Peter had to divide time between them. Perhaps because neither baby received as much attention as the average single infant, Jeannie and Jason walked and talked several months later than most other children their age, though most twins catch up in development by middle childhood (Lytton & Gallagher, 2002; Nan et al., 2013). Parental energies are further strained after the birth of triplets, whose early development is slower than that of twins (Feldman, Eidelman, & Rotenberg, 2004).

## Patterns of Gene–Gene Interactions

Jeannie has her parents’ dark, straight hair; Jason is curly-haired and blond. The way genes from each parent interact helps explain these outcomes. Recall that except for the XY pair in males, all

chromosomes come in matching pairs. Two forms of each gene occur at the same place on the chromosomes, one inherited from the mother and one from the father. Each form of a gene is called an **allele**. If the alleles from both parents are alike, the child is **homozygous** and will display the inherited trait. If the alleles differ, then the child is **heterozygous**, and relationships between the alleles influence the phenotype.

**Dominant–Recessive Pattern.** In many heterozygous pairings, **dominant–recessive inheritance** occurs: Only one allele affects the child’s characteristics. It is called *dominant*; the second allele, which has no effect, is called *recessive*. Hair color is an example. The allele for dark hair is dominant (we can represent it with a capital *D*), whereas the one for blond hair is recessive (symbolized by a lowercase *b*). A child who inherits a homozygous pair of dominant alleles (*DD*) and a child who inherits a heterozygous pair (*Db*) will both be dark-haired, even though their genotypes differ. Blond hair (like Jason’s) can result only from having two recessive alleles (*bb*). Still, heterozygous individuals with just one recessive allele (*Db*) can pass that trait to their children. Therefore, they are called **carriers** of the trait.

Most recessive alleles—like those for blond hair, pattern baldness, or nearsightedness—are of little developmental importance. But as Table 2.2 illustrates, some cause serious disabilities and diseases. One well-known recessive disorder is *phenylketonuria*, or *PKU*, which affects the way the body breaks down proteins contained in many foods. Infants born with two recessive alleles lack an enzyme that converts one of the basic amino acids that make up proteins (phenylalanine) into a byproduct essential for body functioning (tyrosine). Without this enzyme, phenylalanine quickly builds to toxic levels that damage the central nervous system. By 1 year, infants with PKU suffer from permanent intellectual disability.

Despite its potentially damaging effects, PKU illustrates that inheriting unfavorable genes does not always lead to an untreatable condition. All U.S. states require that each newborn be given a blood test for PKU. If the disease is found, doctors place the baby on a diet low in phenylalanine. Children who receive this treatment nevertheless show mild deficits in certain cognitive skills, such as memory, planning, decision making, and problem solving, because even small amounts of phenylalanine interfere with brain functioning (DeRoche & Welsh, 2008; Fonnesbeck et al., 2013). But as long as dietary treatment begins early and continues, children with PKU usually attain an average level of intelligence and have a normal lifespan.

In dominant–recessive inheritance, if we know the genetic makeup of the parents, we can predict the percentage of children in a family who are likely to display or carry a trait. Figure 2.3 on page 48 illustrates this for PKU. For a child to inherit the condition, each parent must have a recessive allele. But because of the action of regulator genes, children vary in the degree to which phenylalanine accumulates in their tissues and in the extent to which they respond to treatment.

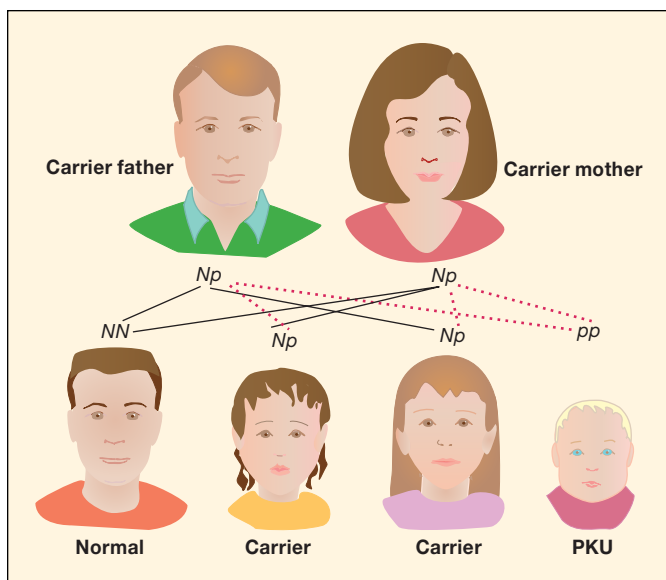

Only rarely are serious diseases due to dominant alleles. Think about why this is so. Children who inherit the dominant

**TABLE 2.2**  
**Examples of Dominant and Recessive Diseases**

DISEASE	DESCRIPTION	MODE OF INHERITANCE	INCIDENCE	TREATMENT
<b>AUTOSOMAL DISEASES</b>				
Cooley's anemia	Pale appearance, retarded physical growth, and lethargic behavior begin in infancy.	Recessive	1 in 500 births to parents of Mediterranean descent	Frequent blood transfusion; death from complications usually occurs by adolescence.
Cystic fibrosis	Lungs, liver, and pancreas secrete large amounts of thick mucus, leading to breathing and digestive difficulties.	Recessive	1 in 2,000 to 2,500 European-American births; 1 in 16,000 births to North Americans of African descent	Bronchial drainage, prompt treatment of respiratory infection, dietary management. Advances in medical care allow survival with good life quality into adulthood.
Phenylketonuria (PKU)	Inability to metabolize the amino acid phenylalanine, contained in many proteins, causes severe central nervous system damage in the first year of life.	Recessive	1 in 10,000 to 20,000 births to North Americans	Placing the child on a special diet results in average intelligence and normal lifespan. Subtle deficits in memory, planning, decision making, and problem solving are often present.
Sickle cell anemia	Abnormal sickling of red blood cells causes oxygen deprivation, pain, swelling, and tissue damage. Anemia and susceptibility to infections, especially pneumonia, occur.	Recessive	1 in 500 births to North Americans of African descent	Blood transfusions, painkillers, prompt treatment of infection. No known cure; 50 percent die by age 55.
Tay-Sachs disease	Central nervous system degeneration, with onset at about 6 months, leads to poor muscle tone, blindness, deafness, and convulsions.	Recessive	1 in 3,600 births to Jews of European descent and to French Canadians	None. Death occurs by 3 to 4 years of age.
Huntington's disease	Central nervous system degeneration leads to muscular coordination difficulties, mental deterioration, and personality changes. Symptoms usually do not appear until age 35 or later.	Dominant	1 in 18,000 to 25,000 births to North Americans	None. Death occurs 10 to 20 years after symptom onset.
Marfan syndrome	Tall, slender build; thin, elongated arms and legs; and heart defects and eye abnormalities, especially of the lens. Excessive lengthening of the body results in a variety of skeletal defects.	Dominant	1 in 5,000 to 10,000 births	Correction of heart and eye defects is sometimes possible. Death from heart failure in young adulthood is common.
<b>X-LINKED DISEASES</b>				
Duchenne muscular dystrophy	Degenerative muscle disease. Abnormal gait, loss of ability to walk between 7 and 13 years.	Recessive	1 in 3,000 to 5,000 male births	None. Death from respiratory infection or weakening of the heart muscle usually occurs in adolescence.
Hemophilia	Blood fails to clot normally; can lead to severe internal bleeding and tissue damage.	Recessive	1 in 4,000 to 7,000 male births	Blood transfusions. Safety precautions to prevent injury.
Diabetes insipidus	Insufficient production of the hormone vasopressin results in excessive thirst and urination. Dehydration can cause central nervous system damage.	Recessive	1 in 2,500 male births	Hormone replacement.

*Note:* For recessive disorders listed, carrier status can be detected in prospective parents through a blood test or genetic analyses. For all disorders listed, prenatal diagnosis is available (see page 53).

*Sources:* Kliegman et al., 2015; Lashley, 2007; National Center for Biotechnology Information, 2015.

**FIGURE 2.3** Dominant–recessive mode of inheritance, as illustrated by PKU. When both parents are heterozygous carriers of the recessive gene ( $p$ ), we can predict that 25 percent of their offspring are likely to be normal ( $NN$ ), 50 percent are likely to be carriers ( $Np$ ), and 25 percent are likely to inherit the disorder ( $pp$ ). Notice that the PKU-affected child, in contrast to his siblings, has light hair. The recessive gene for PKU affects more than one trait. It also leads to fair coloring.

allele always develop the disorder. They seldom live long enough to reproduce, so the harmful dominant allele is eliminated from the family's heredity in a single generation. Some dominant disorders, however, do persist. One is *Huntington's disease*, a condition in which the central nervous system degenerates. Its symptoms usually do not appear until age 35 or later, after the person has passed the dominant allele to his or her children.

**Incomplete-Dominance Pattern.** In some heterozygous circumstances, the dominant–recessive relationship does not hold completely. Instead, we see **incomplete dominance**, a pattern of inheritance in which both alleles are expressed in the phenotype, resulting in a combined trait, or one that is intermediate between the two.

The *sickle cell trait*, a heterozygous condition present in many black Africans, provides an example. *Sickle cell anemia* (see Table 2.2) occurs in full form when a child inherits two recessive genes. They cause the usually round red blood cells to become sickle (crescent-moon) shaped, especially under low-oxygen conditions. The sickled cells clog the blood vessels and block the flow of blood, causing intense pain, swelling, and tissue damage. Despite medical advances that today allow 85 percent of affected children to survive to adulthood, North Americans with sickle cell anemia have an average life expectancy of only 55 years (Chakravorty & Williams, 2015). Heterozygous individuals are protected from the disease under most circumstances. However, when they experience oxygen deprivation—for example, at high altitudes or after intense physical exercise—the single recessive allele asserts itself, and a temporary, mild form of the illness occurs.

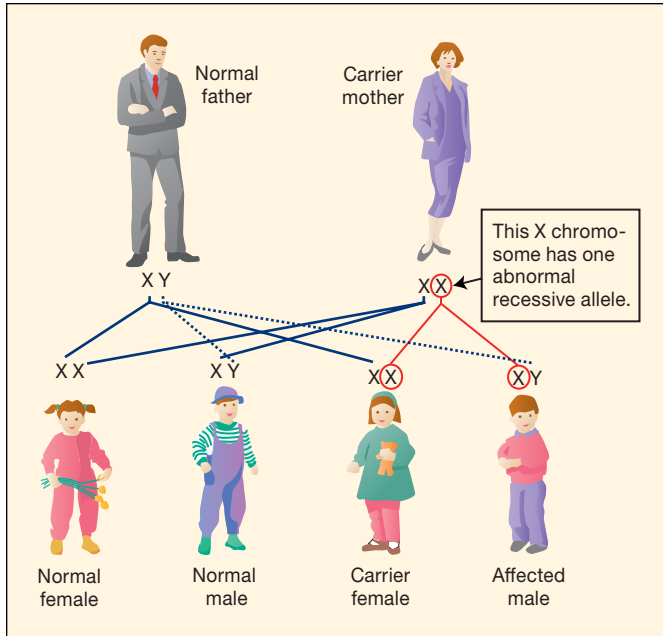

The sickle cell allele is common among black Africans for a special reason. Carriers of it are more resistant to malaria than are individuals with two alleles for normal red blood cells. In Africa, where malaria is common, these carriers survived and reproduced more frequently than others, leading the gene to be maintained in the black population. But in regions of the world where the risk of malaria is low, the frequency of the gene is declining. For example, only 8 percent of African Americans are carriers, compared with 20 percent of black Africans (Centers for Disease Control and Prevention, 2015m).

**X-Linked Pattern.** Males and females have an equal chance of inheriting recessive disorders carried on the autosomes, such as PKU and sickle cell anemia. But when a harmful allele is carried on the X chromosome, **X-linked inheritance** applies. Males are more likely to be affected because their sex chromosomes do not match. In females, any recessive allele on one X chromosome has a good chance of being suppressed by a dominant allele on the other X. But the Y chromosome is only about one-third as long and therefore lacks many corresponding genes to override those on the X. A well-known example is *hemophilia*, a disorder in which the blood fails to clot normally. Figure 2.4 shows its greater likelihood of inheritance by male children whose mothers carry the abnormal allele.

Besides X-linked disorders, many sex differences reveal the male to be at a disadvantage. Rates of miscarriage, infant and childhood deaths, birth defects, learning disabilities, behavior disorders, and intellectual disability all are higher for boys (Boyle et al., 2011; MacDorman & Gregory, 2015). It is possible that these sex differences can be traced to the genetic code. The female, with two X chromosomes, benefits from a greater variety of genes. Nature, however, seems to have adjusted for the male's disadvantage. Worldwide, about 103 boys are born for every 100 girls, and judging from miscarriage and abortion statistics, an even greater number of males are conceived (United Nations, 2015).

In cultures with strong gender-biased attitudes that induce expectant parents to prefer a male child, the male-to-female birth sex ratio is often much larger. In China, for example, the spread of ultrasound technology (which enables prenatal sex determination) and enforcement of a one-child family policy to control population growth—both of which began in the 1980s—led to a dramatic increase in sex-selective abortion. In 2015, China announced the end of its one-child policy, substituting a two-child policy. Nevertheless, many Chinese couples continue to say they desire just one child (Basten & Jiang, 2015; Chen, Li, & Meng, 2013). Today, China's birth sex ratio is 117 boys for every 100 girls—a gender imbalance with adverse social consequences, such as rising crime rates and male competition for marriage partners.

In contrast, in many Western countries, including the United States, Canada, and European nations, the proportion of male births has declined in recent decades. Some researchers attribute this trend to a rise in stressful living conditions, which heighten spontaneous abortions, especially of male fetuses (Catalano et al., 2010). In support of this hypothesis, a California study spanning the decade of the 1990s revealed that the percentage of male fetal

**FIGURE 2.4 X-linked inheritance.** In the example shown here, the allele on the father's X chromosome is normal. The mother has one normal and one abnormal recessive allele on her X chromosomes. By looking at the possible combinations of the parents' alleles, we can predict that 50 percent of these parents' male children are likely to have the disorder and 50 percent of their female children are likely to be carriers of it.

deaths increased in months in which unemployment (a major stressor) also rose above its typical level (Catalano et al., 2009).

**Genomic Imprinting.** More than 1,000 human characteristics follow the rules of dominant–recessive and incomplete-dominance inheritance (National Center for Biotechnology Information, 2015). For these traits, whichever parent contributes a gene to the new individual, the gene responds similarly. Geneticists, however, have identified some exceptions. In **genomic imprinting**, alleles are imprinted, or chemically marked through regulatory processes within the genome, in such a way that one pair member (either the mother's or the father's) is activated, regardless of its makeup (Hirasawa & Feil, 2010). The imprint is often temporary; it may be erased in the next generation, and it may not occur in all individuals.

The number of genes subjected to genomic imprinting is believed to be small—less than 1 percent. Nevertheless, these genes have a significant impact on brain development and physical health, as disruptions in imprinting reveal. For example, imprinting is involved in several childhood cancers and in *Prader-Willi syndrome*, a disorder with symptoms of intellectual disability and severe obesity. Imprinting also may explain why children are more likely to develop diabetes if their father, rather than their mother, suffers from it, and why people with asthma or hay fever tend to have mothers, not fathers, with the illness (Ishida & Moore, 2013).

Genomic imprinting can operate on the sex chromosomes, as *fragile X syndrome*—the most common inherited cause of intellectual disability—reveals. In this disorder, which affects about

1 in 4,000 males and 1 in 6,000 females, an abnormal repetition of a sequence of DNA bases occurs on the X chromosome, damaging a particular gene. In addition to cognitive impairments, the majority of individuals with fragile X syndrome suffer from attention deficits and high anxiety, and about 30 to 35 percent also have symptoms of autism (Wadell, Hagerman, & Hessler, 2013). The defective gene at the fragile site is expressed only when it is passed from mother to child (Hagerman et al., 2009). Because the disorder is X-linked, males are more severely affected.

**Mutation.** Although less than 3 percent of pregnancies result in the birth of a baby with a hereditary abnormality, these children account for about 20 percent of infant deaths and contribute substantially to lifelong impaired physical and mental functioning (Martin et al., 2015). How are harmful genes created in the first place? The answer is **mutation**, a sudden but permanent change in a segment of DNA. A mutation may affect only one or two genes, or it may involve many genes, as in the chromosomal disorders we will discuss shortly. Some mutations occur spontaneously, simply by chance. Others are caused by hazardous environmental agents.

Although nonionizing forms of radiation—electromagnetic waves and microwaves—have no demonstrated impact on DNA, ionizing (high-energy) radiation is an established cause of mutation. Women who receive repeated doses before conception are more likely to miscarry or give birth to children with hereditary defects. The incidence of genetic abnormalities, such as physical malformations and childhood cancer, is also higher in children whose fathers are exposed to radiation in their occupation. However, infrequent and mild exposure to radiation generally does not cause genetic damage (Adelstein, 2014). Rather, moderate to high doses over an extended time can impair DNA.

The examples just given illustrate *germline mutation*, which takes place in the cells that give rise to gametes. When the affected individual mates, the defective DNA is passed on to the next generation. In a second type, called *somatic mutation*, normal body cells mutate, an event that can occur at any time of life. The DNA defect appears in every cell derived from the affected body cell, eventually becoming widespread enough to cause disease (such as cancer) or disability.

It is easy to see how disorders that run in families can result from germline mutation. But somatic mutation may be involved in these disorders as well. Some people harbor a genetic susceptibility that causes certain body cells to mutate easily in the presence of triggering events (Weiss, 2005). This helps explain why some individuals develop serious illnesses (such as cancer) as a result of smoking, exposure to pollutants, or psychological stress, while others do not.

Somatic mutation shows that each of us does not have a single, permanent genotype. Rather, the genetic makeup of each cell can change over time. Somatic mutation increases with age, raising the possibility that it contributes to the age-related rise in disease and to the aging process itself (Salvioli et al., 2008).

Finally, although virtually all mutations that have been studied are harmful, some spontaneous ones (such as the sickle cell allele in malaria-ridden regions of the world) are necessary and

desirable. By increasing genetic variation, they help individuals adapt to unexpected environmental challenges. Scientists, however, seldom go looking for mutations that contribute to favorable traits, such as an exceptional talent or sturdy immune system. They are far more concerned with identifying and eliminating unfavorable genes that threaten health and survival.

**Polygenic Inheritance.** So far, we have discussed patterns of gene–gene interaction in which people either display a particular trait or do not. These cut-and-dried individual differences are much easier to trace to their genetic origins than are characteristics that vary on a continuum among people, such as height, weight, intelligence, and personality. These traits are due to **polygenic inheritance**, in which many genes affect the characteristic in question. Polygenic inheritance is complex, and much about it is still unknown. In the final section of this chapter, we will discuss how researchers infer the influence of heredity on human attributes when they do not know the precise patterns of inheritance.

## Chromosomal Abnormalities

Besides harmful recessive alleles, abnormalities of the chromosomes are a major cause of serious developmental problems. Most chromosomal defects result from mistakes during meiosis, when the ovum and sperm are formed. A chromosome pair does not separate properly or part of a chromosome breaks off. Because these errors involve far more DNA than problems due to single genes, they usually produce many physical and mental symptoms.

**Down Syndrome.** The most common chromosomal disorder, occurring in 1 out of every 700 live births, is *Down syndrome*. In 95 percent of cases, it results from a failure of the twenty-first pair of chromosomes to separate during meiosis, so the new individual receives three of these chromosomes rather than the normal two. For this reason, Down syndrome is sometimes called *trisomy 21*. In other, less frequent forms, an extra broken piece of a twenty-first chromosome is attached to another chromosome (called *translocation* pattern). Or an error occurs during early prenatal cell duplication, causing some but not all body cells to have the defective chromosomal makeup (called *mosaic* pattern) (U.S. Department of Health and Human Services, 2015f). Because the mosaic type involves less genetic material, symptoms may be less extreme.

The consequences of Down syndrome include intellectual disability, memory and speech problems, limited vocabulary, and slow motor development. Measures of electrical brain activity indicate that the brains of individuals with Down syndrome function in a less coordinated fashion than do the brains of typical individuals (Ahmadlou et al., 2013). The disorder is also associated with distinct physical features—a short, stocky build, a flattened face, a protruding tongue, almond-shaped eyes, and (in 50 percent of cases) an unusual crease running across the palm of the hand. In addition, infants with Down syndrome are often born with eye cataracts, hearing loss, and heart and intestinal defects (U.S. Department of Health and Human Services, 2015f).

© LAURA DWIGHT PHOTOGRAPHY

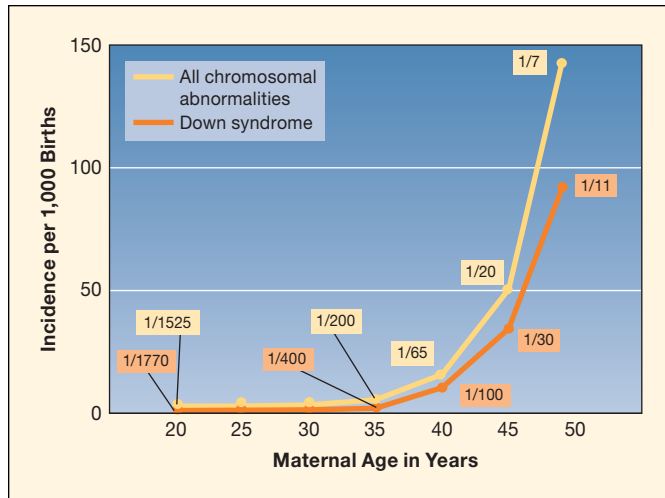

An 8-year-old with Down syndrome, at right, plays with a typically developing classmate. Despite impaired intellectual development, this child benefits from exposure to stimulating environments and from opportunities to interact with peers.

Because of medical advances, life expectancy of individuals with Down syndrome has increased greatly: Today, it is about 60 years of age. However, about 70 percent of affected people who live past age 40 show symptoms of *Alzheimer's disease*, the most common form of dementia (Hartley et al., 2015). Genes on chromosome 21 are linked to this disorder.

Infants with Down syndrome smile less readily, show poor eye-to-eye contact, have weak muscle tone, and explore objects less persistently (Slonims & McConachie, 2006). But when parents encourage them to engage with their surroundings, children with Down syndrome develop more favorably. They also benefit from infant and preschool intervention programs, although emotional, social, and motor skills improve more than intellectual performance (Carr, 2002). Clearly, environmental factors affect how well children with Down syndrome fare.

As Figure 2.5 shows, the risk of bearing a baby with Down syndrome, as well as other chromosomal abnormalities, rises dramatically with maternal age. But exactly why older mothers are more likely to release ova with meiotic errors is not yet known (Chiang, Schultz, & Lampson, 2012). In about 5 percent of cases, the extra genetic material originates with the father. Some studies suggest a role for advanced paternal age, while others show no age effects (De Souza, Alberman, & Morris, 2009; Dzurova & Pikhart, 2005; Vranekovic et al., 2012).

**Abnormalities of the Sex Chromosomes.** Disorders of the autosomes other than Down syndrome usually disrupt development so severely that miscarriage occurs. When such babies are born, they rarely survive beyond early childhood. In contrast, sex chromosome disorders often are not recognized until adolescence when, in some deviations, puberty is delayed. The most common problems involve the presence of an extra chromosome (either X or Y) or the absence of one X in females.

**FIGURE 2.5 Risk of Down syndrome and all chromosomal abnormalities by maternal age.** Risk rises sharply after age 35. (From R. L. Schonberg, 2012, “Birth Defects and Prenatal Diagnosis,” from *Children with Disabilities*, 7th ed., M. L. Batshaw, N. J. Roizen, & G. R. Lotrechiano, eds., p. 50. Baltimore: Paul H. Brookes Publishing Co, Inc.)

Research has discredited a variety of myths about individuals with sex chromosome disorders. For example, males with *XXY syndrome* are not necessarily more aggressive and antisocial than XY males (Stochholm et al., 2012). And most children with sex chromosome disorders do not suffer from intellectual disability. Rather, their cognitive challenges are usually very specific. Verbal difficulties—for example, with reading and vocabulary—are common among girls with *triple X syndrome* and boys with *Klinefelter syndrome*, both of whom inherit an extra X chromosome. In contrast, girls with *Turner syndrome*, who are missing an X, have trouble with spatial relationships—for example, drawing pictures, telling right from left, following travel directions, and noticing changes in facial expressions (Otter et al., 2013; Ross et al., 2012; Temple & Shephard, 2012). Brain-imaging evidence confirms that adding to or subtracting from the usual number of X chromosomes alters the development of certain brain structures, yielding particular intellectual deficits (Bryant et al., 2012; Hong et al., 2014).

## Ask yourself

**CONNECT** Referring to ecological systems theory (Chapter 1, pages 23–26), explain why parents of children with genetic disorders often experience increased stress. What factors, within and beyond the family, can help these parents support their children’s development?

**APPLY** Gilbert’s genetic makeup is homozygous for dark hair. Jan’s is homozygous for blond hair. What proportion of their children are likely to be dark-haired? Explain.

**REFLECT** Provide illustrations from our discussion, and from people you know with genetic disorders, of environmental influences on development.

## Reproductive Choices

### 2.4 What procedures can assist prospective parents in having healthy children?

Two years after they married, Ted and Marianne gave birth to their first child. Kendra appeared to be a healthy infant, but by 4 months her growth had slowed, and she was diagnosed with Tay-Sachs disease (see Table 2.2 on page 47). When Kendra died at 2 years of age, Ted and Marianne were devastated. Although they did not want to bring another infant into the world who would endure such suffering, they badly wanted to have a child.

In the past, many couples with genetic disorders in their families chose not to bear a child at all rather than risk the birth of an abnormal baby. Today, genetic counseling and prenatal diagnosis help people make informed decisions about conceiving, carrying a pregnancy to term, or adopting a child.

## Genetic Counseling

**Genetic counseling** is a communication process designed to help couples assess their chances of giving birth to a baby with a hereditary disorder and choose the best course of action in view of risks and family goals. Individuals likely to seek counseling are those who have had difficulties bearing children—for example, repeated miscarriages—or who know that genetic problems exist in their families. In addition, adults who delay childbearing are often candidates for genetic counseling. As maternal age rises beyond age 35, the rates of Down syndrome and other chromosomal abnormalities increase sharply (refer again to Figure 2.5). Older paternal age presents a heightened risk of DNA mutations as well. After age 40, it is associated with increased incidence of several serious psychological disorders (Zitzmann, 2013). These include *autism* (see page 21 in Chapter 1); *schizophrenia*, characterized by hallucinations, delusions, and irrational behavior; and *bipolar disorder*, marked by alternating periods of elation and depression. But because younger parents have children in far higher numbers than older parents, they still bear the majority of babies with genetic defects. Therefore, some experts argue that parental needs, not age, should determine referral for genetic counseling (Berkowitz, Roberts, & Minkoff, 2006).

If a family history of intellectual disability, psychological disorders, physical defects, or inherited diseases exists, the genetic counselor interviews the couple and prepares a *pedigree*, a picture of the family tree in which affected relatives are identified. The pedigree is used to estimate the likelihood that parents will have an affected child. For many disorders traceable to a single gene, blood tests or genetic analyses can reveal whether the parent is a carrier of the harmful allele. Carrier detection is possible for all the recessive diseases listed in Table 2.2 on page 47, as well as others, and for fragile X syndrome.

Autism, schizophrenia, and bipolar disorder have each been linked to an array of DNA-sequence deviations (called *genetic*

## Social Issues: Health

### The Pros and Cons of Reproductive Technologies

Some people decide not to risk pregnancy because of a history of genetic disease. Many others—in fact, one-sixth of all couples who try to conceive—discover that they are infertile. And some never-married adults and gay and lesbian couples want to bear children. Today, increasing numbers of individuals are turning to alternative methods of conception—technologies that have become the subject of heated debate.

#### Donor Insemination and In Vitro Fertilization

For nearly fifty years, *donor insemination*—injection of sperm from an anonymous man into a woman—has been used to overcome male reproductive difficulties. It also permits women without a male partner to become pregnant. Donor insemination is 70 percent successful, resulting in about 40,000 deliveries and 52,000 newborn babies in the United States each year (Rossi, 2014).

*In vitro fertilization* is another commonly used reproductive technology. Since the first “test tube” baby was born in England in 1978, 1 percent of all children in developed countries—about 65,000 babies in the United States—have been conceived through this technique annually (Sunderam et al., 2015). With in vitro fertilization, a woman is given hormones that stimulate the ripening of several ova. These are removed surgically and placed in a dish of nutrients, to which sperm are added. Once an ovum is fertilized and duplicates into several cells, it is injected into the mother’s uterus.

By mixing and matching gametes, pregnancies can be brought about when either or both partners have a reproductive problem. Usually, in vitro fertilization is used to treat women whose fallopian tubes are permanently damaged. But a single sperm can now be injected directly into an ovum, thereby overcoming most male fertility problems. And a “sex sorter” method helps ensure that couples who carry X-linked diseases (which usually affect males) have a daughter. Fertilized ova and sperm can even be frozen and stored in embryo banks for use at some future time, thereby guaranteeing healthy zygotes should age or illness lead to fertility problems.

The overall success rate of assisted reproductive techniques, as measured by live births, is about 50 percent. However, success declines steadily with age, from 55 percent in women age 31 to 35 to 8 percent in women age 43 (Cetinkaya, Siano, & Benadiva, 2013; Gnath et al., 2011).

Children conceived through these methods may be genetically unrelated to one or both of their parents. In addition, most parents who have used the procedures do not tell their children how they were conceived. Does lack of genetic ties or secrecy interfere with parent–child relationships? Perhaps because of a strong desire for parenthood, caregiving is actually somewhat warmer for young children conceived through donor insemination or in vitro fertilization. Also, these children and adolescents are as well-adjusted as their counterparts who were naturally conceived

(Punamäki, 2006; Wagenaar et al., 2011). However, in one study, school-age children who had not been informed of their gamete-donor origins experienced less positive maternal interaction (Golombok et al., 2011, 2013). This suggests that open discussion can be helpful to families.

Although reproductive technologies have many benefits, serious questions have arisen about their use. In many countries, including the United States, doctors are not required to keep records of donor characteristics, though information about the child’s genetic background might be critical in the case of serious disease (Murphy, 2013). Another concern is that the in vitro “sex sorter” method enables parental sex selection, thereby eroding the moral value that boys and girls are equally precious.

In vitro fertilization poses greater risks than natural conception to infant survival and healthy development. About 26 percent of in vitro procedures result in multiple births. Most are twins, but 3 percent are triplets and higher-order multiples. Consequently, among in vitro babies, the rate of low birth weight is nearly four times as high as in the general population. In response, doctors have reduced the number of fertilized ova injected into a woman’s uterus, typically to no more than two (Kulkarni et al., 2013; Sunderam et al., 2015). Risk of pregnancy complications, miscarriage, and major birth defects also rises, due to the biological effects of in vitro techniques and the older age of many people seeking treatment.

markers) distributed across multiple chromosomes. New *genomewide testing methods*, which look for these genetic markers, enable genetic counselors to estimate risk for these conditions. But estimates are generally low because the genetic markers are found in only a minority of affected people. Also, the genetic markers are not associated with mental illness every time they appear. Their expression—as we will illustrate at the end of this chapter—seems to depend on environmental conditions. Recently, geneticists have begun to identify rare repeats and

deletions of DNA bases that are more consistently related to mental illness (Gershon & Alliey-Rodriguez, 2013). These discoveries may lead to more accurate prediction of the likelihood of passing a psychological disorder from parent to child.

When all the relevant hereditary information is in, genetic counselors help people consider appropriate options. These include taking a chance and conceiving, choosing from among a variety of reproductive technologies (see the Social Issues: Health box above), or adopting a child.

### Surrogate Motherhood

An even more controversial form of medically assisted conception is *surrogate motherhood*. In this procedure, in vitro fertilization may be used to impregnate a woman (called a surrogate) with a couple's fertilized ovum. Alternatively, sperm from a man whose partner is infertile may be used to inseminate the surrogate, who agrees to turn the baby over to the father. The child is then adopted by his partner. In both cases, the surrogate is paid a fee for her childbearing services.

Most surrogate arrangements proceed smoothly, and the limited evidence available suggests that families usually function well, tell their children about the surrogacy, and stay in touch with and have positive relationships with the surrogate, especially if she is genetically related to the child (Golombok et al., 2011, 2013; Jadva, Casey, & Golombok, 2012). The small number of children who have been studied are generally well-adjusted.

Nevertheless, because surrogacy usually involves the wealthy as contractors for infants and the less economically advantaged as surrogates, it may promote exploitation of financially needy women. In addition, most surrogates already have children of their own, and knowledge that their mother would give away a baby may cause these children to worry about the security of their own family circumstances.

### Reproductive Frontiers

Experts are debating the ethics of other reproductive options. Doctors have used donor ova from younger women in combination with in vitro fertilization to help postmenopausal women become pregnant. Most recipients are

in their forties, but some in their fifties and sixties, and a few at age 70, have given birth. These cases magnify health risks to mother and baby and bring children into the world whose parents may not live to see them reach adulthood. Based on U.S. life expectancy data, 1 in 3 mothers and 1 in 2 fathers having a baby at age 55 will die before their child enters college (U.S. Census Bureau, 2015d).

Today, customers at donor banks can select ova or sperm on the basis of physical characteristics and even IQ. And scientists are devising ways to alter the DNA of human ova, sperm, and embryos to protect against hereditary disorders—techniques that could be used to engineer other desired characteristics. Many worry that these practices are dangerous steps toward selective breeding through “designer babies”—controlling offspring traits by manipulating genetic makeup.

Although reproductive technologies permit many barren adults to become parents, laws are needed to regulate such practices. In Australia, New Zealand, and Europe, in vitro gamete donors and applicants for the procedure must undergo highly regulated screening (Murphy, 2013). Denmark, France, and Italy prohibit in vitro fertilization for women past

Fertility drugs and in vitro fertilization often lead to multiple births. These quadruplets are healthy, but babies born with the aid of reproductive technologies are at high risk for low birth weight and major birth defects.

menopause. Pressure from those working in the field of assisted reproduction may soon lead to similar policies in the United States.

The ethical problems of surrogate motherhood are so complex that 13 U.S. states and the District of Columbia sharply restrict or ban the practice (Swain, 2014). Most European nations, along with Australia and Canada, allow only “altruistic” surrogacy, in which the surrogate has no financial gain. At present, not enough is known about the consequences of being a product of these procedures. More research on how such children grow up, including later-appearing medical conditions and feelings about their origins, is important for weighing the pros and cons of these techniques.

## Prenatal Diagnosis and Fetal Medicine

If couples at risk for bearing a child with abnormalities decide to conceive, several **prenatal diagnostic methods**—medical procedures that permit detection of developmental problems before birth—are available (see Table 2.3 on page 54). Women of advanced maternal age are prime candidates for *amniocentesis* or *chorionic villus sampling*. Except for *maternal blood analysis*,

however, prenatal diagnosis should not be used routinely because of injury risks to the developing organism.

Prenatal diagnosis has led to advances in fetal medicine. For example, by inserting a needle into the uterus, doctors can administer drugs to the fetus. Surgery has been performed to repair such problems as heart, lung, and diaphragm malformations, urinary tract obstructions, and neural defects (Sala et al., 2014). Fetuses with blood disorders have been given blood transfusions. And those with immune deficiencies have received bone

**TABLE 2.3**  
**Prenatal Diagnostic Methods**

METHOD	DESCRIPTION
Amniocentesis	The most widely used technique. A hollow needle is inserted through the abdominal wall to obtain a sample of fluid in the uterus. Cells are examined for genetic defects. Can be performed by the 14th week after conception; 1 to 2 more weeks are required for test results. Small risk of miscarriage.
Chorionic villus sampling	A procedure that can be used if results are desired or needed very early in pregnancy. A thin tube is inserted into the uterus through the vagina, or a hollow needle is inserted through the abdominal wall. A small plug of tissue is removed from the end of one or more chorionic villi, the hairlike projections on the membrane surrounding the developing organism. Cells are examined for genetic defects. Can be performed at 9 weeks after conception; results are available within 24 hours. Entails a slightly greater risk of miscarriage than amniocentesis. Also associated with a small risk of limb deformities, which increases the earlier the procedure is performed.
Fetoscopy	A small tube with a light source at one end is inserted into the uterus to inspect the fetus for defects of the limbs and face. Also allows a sample of fetal blood to be obtained, permitting diagnosis of such disorders as hemophilia and sickle cell anemia, as well as neural defects (see below). Usually performed between 15 and 18 weeks after conception but can be done as early as 5 weeks. Entails some risk of miscarriage.
Ultrasound	High-frequency sound waves are beamed at the uterus; their reflection is translated into a picture on a video screen that reveals the size, shape, and placement of the fetus. By itself, permits assessment of fetal age, detection of multiple pregnancies, and identification of gross physical defects. Also used to guide amniocentesis, chorionic villus sampling, and fetoscopy. Sometimes combined with magnetic resonance imaging (see below) to detect physical abnormalities with greater accuracy. When used five or more times, may increase the chances of low birth weight.
Maternal blood analysis	By the second month of pregnancy, some of the developing organism's cells enter the maternal bloodstream. An elevated level of alpha-fetoprotein may indicate kidney disease, abnormal closure of the esophagus, or neural tube defects, such as anencephaly (absence of most of the brain) and spina bifida (bulging of the spinal cord from the spinal column). Isolated cells can be examined for genetic defects.
Ultrafast magnetic resonance imaging (MRI)	Sometimes used as a supplement to ultrasound, where brain or other abnormalities are detected and MRI can provide greater diagnostic accuracy. Uses a scanner to magnetically record detailed pictures of fetal structures. The ultrafast technique overcomes image blurring due to fetal movements. No evidence of adverse effects.
Preimplantation genetic diagnosis	After in vitro fertilization and duplication of the zygote into a cluster of about 8 to 10 cells, 1 or 2 cells are removed and examined for hereditary defects. Only if that sample is free of detectable genetic disorders is the fertilized ovum implanted in the woman's uterus.

Sources: Akolekar et al., 2015; Jokhi & Whitby, 2011; Kollmann et al., 2013; Moore, Persaud, & Torchia, 2016b; Sermon, Van Steirteghem, & Liebaers, 2004.

marrow transplants that succeeded in creating a normally functioning immune system (Depreest et al., 2010).

These techniques frequently result in complications, the most common being premature labor and miscarriage (Danzer & Johnson, 2014). Yet parents may be willing to try almost any option, even one with only a slim chance of success. Currently, the medical profession is struggling with how to help parents make informed decisions about fetal surgery.

Advances in *genetic engineering* also offer hope for correcting hereditary defects. As part of the Human Genome Project—an ambitious international research program aimed at deciphering the chemical makeup of human genetic material (genome)—researchers mapped the sequence of all human DNA base pairs. Using that information, they are “annotating” the genome—identifying all its genes and their functions, including their protein products and what these products do. A major goal is to understand the estimated 4,000 human disorders, those due to single genes and those resulting from an interplay of multiple genes and environmental factors.

A 9-year-old with cystic fibrosis undergoes a breathing test to assess lung functioning. Today, researchers are testing gene therapies aimed at regenerating the lining of the lungs to relieve symptoms of this recessive disorder.

## Applying what we Know

### Steps Prospective Parents Can Take Before Conception to Increase the Chances of a Healthy Baby

RECOMMENDATION	EXPLANATION
Arrange for a physical exam.	A physical exam before conception permits detection of diseases and other medical problems that might reduce fertility, be difficult to treat during pregnancy, or affect the developing organism.
Consider your genetic makeup.	Find out if anyone in your family has had a child with a genetic disease or disability. If so, seek genetic counseling before conception.
Reduce or eliminate toxins under your control.	Because the developing organism is highly sensitive to damaging environmental agents during the early weeks of pregnancy (see Chapter 3), couples trying to conceive should avoid drugs, alcohol, cigarette smoke, radiation, pollution, chemical substances in the home and workplace, and infectious diseases. Furthermore, they should stay away from ionizing radiation and household and industrial chemicals, which pose risks for mutations.
Ensure proper nutrition.	A doctor-recommended vitamin–mineral supplement, begun before conception, helps prevent many prenatal problems. It should include folic acid, which reduces the chances of neural tube defects, prematurity, and low birth weight (see Chapter 3, pages 87–88).
Consult your doctor after 12 months of unsuccessful efforts at conception.	Long periods of infertility may be due to undiagnosed spontaneous abortions, which can be caused by genetic defects in either partner. If a physical exam reveals a healthy reproductive system, seek genetic counseling.

So far, thousands of genes have been identified, including those involved in disorders of the heart, digestive, blood, eye, and nervous system and in many forms of cancer (National Institutes of Health, 2015). As a result, new treatments are being explored, such as *gene therapy*—correcting genetic abnormalities by delivering DNA carrying a functional gene to the cells. Testing of gene therapies for relieving symptoms of hemophilia and treating severe immune system dysfunction, leukemia, and several forms of cancer has been encouraging (Kaufmann et al., 2013). In another approach, called *proteomics*, scientists modify gene-specified proteins involved in biological aging and disease (Twyman, 2014).

Genetic treatments, however, seem some distance in the future for most single-gene defects and even farther off for diseases involving multiple genes that combine in complex ways with each other and the environment. Applying What We Know above summarizes steps that prospective parents can take before conception to protect the genetic health of their child.

## Adoption

Adults who are infertile or likely to pass along a genetic disorder, same-sex couples, and single adults who want a family are turning to adoption in increasing numbers. Couples who have children by birth, too, sometimes choose to expand their families through adoption. Adoption agencies try to ensure a good fit by seeking parents of the same ethnic and religious background as the child and, where possible, choosing parents who are the same age as typical biological parents. Because the availability of healthy babies has declined (fewer young unwed

mothers give up their babies than in the past), more people in North America and Western Europe are adopting from other countries or accepting children who are past infancy or who have known developmental problems (Palacios & Brodzinsky, 2010).

Adopted children and adolescents—whether or not they are born in their adoptive parents' country—tend to have more learning and emotional difficulties than other children, a difference that increases with the child's age at time of adoption (van den Dries et al., 2009; van IJzendoorn, Juffer, & Poelhuis, 2005;

Adoption is one option for adults who are infertile or have a family history of genetic disorders. This couple, who adopted their daughters from China, can promote their children's adjustment by helping them learn about their birth heritage.

Verhulst, 2008). Various explanations exist for adoptees' more problematic childhoods. The biological mother may have been unable to care for the child because of problems believed to be partly genetic, such as alcoholism or severe depression, and may have passed this tendency to her offspring. Or perhaps she experienced stress, poor diet, or inadequate medical care during pregnancy—factors that can affect the child (as we will see in Chapter 3). Furthermore, children adopted after infancy often have a preadoptive history of conflict-ridden family relationships, lack of parental affection, neglect and abuse, or deprived institutional rearing. Finally, adoptive parents and children, who are genetically unrelated, are less alike in intelligence and personality than are biological relatives—differences that may threaten family harmony.

Despite these risks, most adopted children fare well, and those with preexisting problems who experience sensitive parenting usually make rapid progress, cognitively and socially (Arcus & Chambers, 2008; Juffer & van IJzendoorn, 2012). Overall, international adoptees develop much more favorably than birth siblings or institutionalized agetates who remain in their birth country (Christoffersen, 2012). And children with troubled family histories who are adopted at older ages generally improve in feelings of trust and affection for their adoptive parents as they come to feel loved and supported (Verissimo & Salvaterra, 2006). As we will see in Chapter 4, however, later-adopted children—especially those with multiple early-life adversities—are more likely than their agetates to have persistent cognitive, emotional, and social problems.

By adolescence, adoptees' lives are often complicated by unresolved curiosity about their roots. As they try to integrate aspects of their birth family and their adoptive family into their emerging identity, teenagers face a challenging process of defining themselves. When parents have been warm, open, and supportive in their communication about adoption, their children typically forge a positive sense of self (Brodzinsky, 2011). And as long as their parents took steps to help them learn about their heritage in childhood, young people adopted into a different ethnic group or culture generally develop identities that are healthy blends of their birth and rearing backgrounds (Nickman et al., 2005; Thomas & Tessler, 2007). The decision to search for birth parents, however, is usually postponed until early adulthood, when marriage and childbirth may trigger it.

As we conclude our discussion of reproductive choices, perhaps you are wondering how things turned out for Ted and Marianne. Through genetic counseling, Marianne discovered a history of Tay-Sachs disease on her mother's side of the family. Ted had a distant cousin who died of the disorder. The genetic counselor explained that the chances of giving birth to another affected baby were 1 in 4. Ted and Marianne took the risk: Their son Douglas is now 12 years old. Although Douglas is a carrier of the recessive allele, he is healthy. In a few years, Ted and Marianne will tell Douglas about his genetic history and explain the importance of genetic counseling and testing before he has children of his own.

## Ask yourself

**CONNECT** How does research on adoption reveal resilience? Which factor related to resilience (see Chapter 1, pages 10–11) is central in positive outcomes for adoptees?

**APPLY** Imagine that you must counsel a couple considering in vitro fertilization using donor ova to overcome infertility. What medical and ethical risks would you raise?

**REFLECT** Suppose you are a carrier of fragile X syndrome and want to have children. Would you choose pregnancy, adoption, or surrogacy? If you became pregnant, would you opt for prenatal diagnosis? Explain your decisions.

## Environmental Contexts for Development

**2.5** Describe family functioning from the perspective of ecological systems theory, along with aspects of the environment that support family well-being and development.

Just as complex as genetic inheritance is the surrounding environment—a many-layered set of influences that combine to help or hinder physical and psychological well-being. Jot down a brief description of events and people that have significantly influenced your development. Do the items on your list resemble those of my students, who mostly mention experiences that involve their families? This emphasis is not surprising, since the family is the first and longest-lasting context for development. Other influences that generally make students' top ten are friends, neighbors, school, workplace, and community and religious organizations.

Return to Bronfenbrenner's ecological systems theory, discussed in Chapter 1. It emphasizes that environments extending beyond the *microsystem*—the immediate settings just mentioned—powerfully affect development. Indeed, my students rarely mention one context, with an impact so pervasive that we seldom stop to think about it in our daily lives. This is the *macrosystem*, or broad social climate of society—its values and programs that support and protect human development. All people need help with the demands of each period of the lifespan—through affordable housing and health care, safe neighborhoods, good schools, well-equipped recreational facilities, and high-quality child care and other services that permit them to meet both work and family responsibilities. And some people, because of poverty or special tragedies, need considerably more help than others.

In the following sections, we take up these contexts for development. Because they affect every age and aspect of change, we will return to them in later chapters. For now, our discussion emphasizes that environments, as well as heredity, can enhance or create risks for development.

## The Family

In power and breadth of influence, no other microsystem context equals the family. The family creates unique bonds among people. Attachments to parents and siblings are usually lifelong and serve as models for relationships in the wider world. Within the family, children learn the language, skills, and social and moral values of their culture. And people of all ages turn to family members for information, assistance, and pleasurable interaction. Warm, gratifying family ties predict physical and psychological health throughout development (Khaleque & Rohner, 2012). In contrast, isolation or alienation from the family, especially from parents, is generally associated with developmental problems.

Contemporary researchers view the family as a network of interdependent relationships (Bronfenbrenner & Morris, 2006; Russell, 2014). Recall from ecological systems theory that *bidirectional influences* exist in which the behaviors of each family member affect those of others. Indeed, the very term *system* implies that the responses of family members are related. These system influences operate both directly and indirectly.

**Direct Influences.** The next time you have a chance to observe family members interacting, watch carefully. You are likely to see that kind, patient communication evokes cooperative, harmonious responses, whereas harshness and impatience engender angry, resistive behavior. Each of these reactions, in turn, forges a new link in the interactive chain. In the first instance, a positive message tends to follow; in the second, a negative or avoidant one is likely.

These observations fit with a wealth of research on the family system. Studies of families of diverse ethnicities show that when parents are firm but warm, children tend to comply with their requests. And when children cooperate, their parents are likely to be warm and gentle in the future. In contrast, children whose parents discipline harshly and impatiently are likely to

The family is a network of interdependent relationships, in which each person's behavior influences that of others. As this family plays a game, warm, considerate parental communication encourages children's cooperation, which promotes further parental warmth and caring.

refuse and rebel. And because children's misbehavior is stressful, parents may increase their use of punishment, leading to more unruliness by the child (Lorber & Egeland, 2011; Shaw et al., 2012). This principle also applies to other two-person family relationships—siblings, marital partners, parent and adult child. In each case, the behavior of one family member helps sustain a form of interaction in the other that either promotes or undermines psychological well-being.

**Indirect Influences.** The impact of family relationships on development becomes even more complicated when we consider that interaction between any two members is affected by others present in the setting. Recall from Chapter 1 that Bronfenbrenner calls these indirect influences the effect of *third parties*.

Third parties can serve as supports for or barriers to development. For example, when a marital relationship is warm and considerate, mothers and fathers are more likely to engage in effective **coparenting**, mutually supporting each other's parenting behaviors. Such parents are warmer, praise and stimulate their children more, and nag and scold them less. Effective coparenting, in turn, fosters a positive marital relationship (Morrill et al., 2010). In contrast, parents whose marriage is tense and hostile often coparent ineptly. They interfere with each other's child-rearing efforts, are less responsive to children's needs, and are more likely to criticize, express anger, and punish (Palkovitz, Fagan, & Hull, 2013; Pruett & Donsky, 2011).

Children who are chronically exposed to angry, unresolved parental conflict have serious behavior problems resulting from disrupted emotional security (Cummings & Miller-Graff, 2015). These include both *internalizing difficulties*, such as feeling anxious and fearful and trying to repair their parents' relationship, and *externalizing difficulties*, including anger and aggression (Cummings, Goeke-Morey, & Papp, 2004; Goeke-Morey, Papp, & Cummings, 2013). These child problems can further disrupt the parents' relationship.

Yet even when third parties strain family ties, other members may help restore effective interaction. Grandparents, for example, can promote children's development both directly, by responding warmly to the child, and indirectly, by providing parents with child-rearing advice, models of child-rearing skill, and even financial assistance. Of course, as with any indirect influence, grandparents can sometimes be harmful. When relations between grandparents and parents are quarrelsome, parent-child communication may suffer.

**Adapting to Change.** Think back to the *chronosystem* in Bronfenbrenner's theory (see page 26 in Chapter 1). The interplay of forces within the family is dynamic and ever-changing. Important events, such as the birth of a baby, a change of jobs, or the addition to the household of an aging parent in declining health, create challenges that modify existing relationships. The way such events affect family interaction depends on the support other family members provide and on the developmental status of each participant. For example, the arrival of a new baby prompts

very different reactions in a toddler than in a school-age child. And caring for an ill, aging parent is more stressful for a middle-aged adult still rearing children than for an adult of the same age who has no child-rearing responsibilities.

Historical time period also contributes to a dynamic family system. In recent decades, a declining birth rate, a high divorce rate, expansion of women's roles, increased acceptance of homosexuality, and postponement of parenthood have led to a smaller family size and a greater number of single parents, remarried parents, gay and lesbian parents, employed mothers, and dual-earner families. This, combined with a longer lifespan, means that more generations are alive, with fewer members in the youngest ones, leading to a “top-heavy” family structure. Young people today are more likely to have older relatives than at any time in history—a circumstance that can be enriching as well as a source of tension. In sum, as this complex intergenerational system moves through time, relationships are constantly revised as members adjust to their own and others' development as well as to external pressures.

### LOOK and LISTEN

Record the number of siblings in your grandparents', parents', and own generation. Then do the same for several of your friends' families. Do you see evidence of a “top-heavy” family structure? What consequences might it have for family members of different generations?

Nevertheless, some general patterns in family functioning do exist. In the United States and other industrialized nations, one important source of these consistencies is socioeconomic status.

## Socioeconomic Status and Family Functioning

People in industrialized nations are stratified on the basis of what they do at work and how much they earn for doing it—factors that determine their social position and economic well-being. Researchers assess a family's standing on this continuum through an index called **socioeconomic status (SES)**, which combines three related, but not completely overlapping, variables: (1) years of education and (2) the prestige of one's job and the skill it requires, both of which measure social status; and (3) income, which measures economic status. As SES rises and falls, people face changing circumstances that profoundly affect family functioning.

SES is linked to timing of marriage and parenthood and to family size. People who work in skilled and semiskilled manual occupations (for example, construction workers, truck drivers, and custodians) tend to marry and have children earlier as well as give birth to more children than people in professional and technical occupations. The two groups also differ in child-rearing values and expectations. For example, when asked about per-

sonal qualities they desire for their children, lower-SES parents tend to emphasize external characteristics, such as obedience, politeness, neatness, and cleanliness. In contrast, higher-SES parents emphasize psychological traits, such as curiosity, happiness, self-direction, and cognitive and social maturity (Duncan & Magnuson, 2003; Hoff, Laursen, & Tardif, 2002).

These differences are reflected in family interaction. Parents higher in SES talk to, read to, and otherwise stimulate their infants and preschoolers more and grant them greater freedom to explore. With older children and adolescents, higher-SES parents use more warmth, explanations, and verbal praise; set higher academic and other developmental goals; and allow their children to make more decisions. Commands (“You do that because I told you to”), criticism, and physical punishment all occur more often in low-SES households (Bush & Peterson, 2008; Mandara et al., 2009).

Education contributes substantially to these variations in child rearing. Higher-SES parents' interest in providing verbal stimulation, nurturing inner traits, and promoting academic achievement is supported by years of schooling, during which they learned to think about abstract, subjective ideas and, thus, to invest in their children's cognitive and social development (Mistry et al., 2008). At the same time, greater economic security enables parents to devote more time, energy, and material resources to fostering their children's psychological characteristics (Duncan, Magnuson, & Votruba-Drzal, 2015).

Because of limited education and low social status, many lower-SES parents feel a sense of powerlessness in their relationships beyond the home. At work, for example, they must obey rules made by others in positions of authority. When they get home, their parent-child interaction seems to duplicate these experiences—but now they are in authority. High levels of stress sparked by economic insecurity contribute to low-SES parents' reduced provision of stimulating interaction and activities as well as greater use of coercive discipline (Belsky, Schlomer, & Ellis, 2012; Conger & Donnellan, 2007). Higher-SES parents, in contrast, typically have more control over their own lives. At work, they are used to making independent decisions and convincing others of their point of view. At home, they are more likely to teach these skills to their children.

## Poverty

When families slip into poverty, development is seriously threatened. In a TV documentary on childhood poverty, a PBS filmmaker explored the daily lives of several American children, along with the struggles of their families (Frontline, 2012). Asked what being poor is like, 10-year-old Kaylie replied, “We don't get three meals a day. . . . Sometimes we have cereal but no milk and have to eat it dry.” Kaylie said she felt hungry much of the time, adding, “I'm afraid if we can't pay our bills, me and my brother will starve.”

Kaylie lives with her 12-year-old brother Tyler and their mother, who suffers from depression and panic attacks and cannot work. The children sometimes gather discarded tin cans from around their rural neighborhood and sell them for a small amount

Homelessness poses enormous challenges for maintaining positive family relationships and physical and mental health. This mother and her three young children prepare to move out of the motel room they share with her boyfriend and father.

of cash. When money to pay rent ran out, the family moved from its small house to an extended-stay motel. Before the move, Kaylie and Tyler tearfully gave up their pet dog to a shelter.

In the cramped motel room with family belongings piled haphazardly around her, Kaylie complained, “I have no friends, no places to play. I pass the time by.” Her mother had postponed the children’s school enrollment, expecting soon to move to a trailer court in a new school district. Kaylie and Tyler had few books and indoor games; no outdoor play equipment such as bicycles, bats and balls, and roller skates; and no scheduled leisure pursuits like swimming or music lessons or youth organization activities. Asked to imagine her future, Kaylie wasn’t hopeful. “I see my future poor, on the streets, in a box, asking for money from everyone, stealing stuff. . . . I’d like to explore the world, but I’m never going to be able to do that.”

Although poverty rates in the United States declined slightly in the 1990s, they rose over the first decade of the twenty-first century and then stabilized. Today, about 15 percent—46 million Americans—are affected. Those hit hardest are parents under age 25 with young children and older adults who live alone. Poverty is also magnified among ethnic minorities and women. For example, 21 percent of U.S. children are poor, a rate that climbs to 32 percent for Hispanic children, 36 percent for Native-American children, and 38 percent for African-American children. For single mothers with preschool children and older women on their own, the poverty rate is close to 50 percent (U.S. Census Bureau, 2015d).

Joblessness, a high divorce rate, a lower remarriage rate among women than men, widowhood, and (as we will see later) government programs with insufficient resources to meet family needs are responsible for these disheartening statistics. The poverty rate is higher among children than any other age group. And of all Western nations, the United States has the highest per-

centage of extremely poor children. Nearly 10 percent of U.S. children live in deep poverty (at less than half the poverty threshold, the income level judged necessary for a minimum living standard). In contrast, in most northern and central European countries, child poverty rates have remained below 10 percent for several decades, and extreme child poverty is rare (UNICEF, 2013). The earlier poverty begins, the deeper it is, and the longer it lasts, the more devastating are its effects. Children of poverty are more likely than other children to suffer from lifelong poor physical health, persistent deficits in cognitive development and academic achievement, high school dropout, mental illness, and impulsivity, aggression, and antisocial behavior (Duncan, Magnuson, & Votruba-Drzal, 2015; Morgan et al., 2009; Yoshikawa, Aber, & Beardslee, 2012).

The constant stressors that accompany poverty gradually weaken the family system. Poor families have many daily hassles: loss of welfare and unemployment payments, basic services—phone, TV, electricity, hot water—being shut off because of inability to pay bills, and limited or uncertain access to food, to name just a few. When daily crises arise, family members become depressed, irritable, and distracted; hostile interactions increase; and children’s development suffers (Conger & Donnellan, 2007; Kohen et al., 2008).

Negative outcomes are especially severe in single-parent families and families who must live in poor housing and dangerous neighborhoods—conditions that make everyday existence even more difficult while reducing social supports that help people cope with economic hardship (Hart, Atkins, & Matsuba, 2008; Leventhal, Dupéré, & Shuey, 2015). On average, poverty rates are higher, neighborhood disorganization greater, and community services scarcer in rural communities—like the one where Kaylie, Tyler, and their mother live—than in urban areas (Hicken et al., 2014; Vernon-Feagans & Cox, 2013). These conditions heighten risks for disrupted family functioning and physical and psychological adjustment throughout life.

A related problem has reduced the life chances of substantial numbers of children and adults. An estimated 580,000 individuals in the United States were homeless on a given night in the most recently reported year (Henry et al., 2014). The majority are adults on their own, many of whom suffer from serious mental illness. But about one-fourth of the homeless are children and youths. Homelessness is mostly due to two factors: insufficient availability of low-cost housing and release of people with mental illness from institutions without necessary supports for adjusting to ordinary life.

Most homeless families consist of women with children under age 5. Besides health problems (which affect the majority of homeless people), many homeless children suffer from developmental delays and chronic emotional stress due to harsh, insecure daily lives (Kilmer et al., 2012). An estimated 23 percent who are old enough do not go to school, or attend irregularly. Homeless children achieve less well than other poverty-stricken children because of poor attendance, frequent moves from school to school, and physical and emotional health problems (Cutuli et al., 2010; National Coalition for the Homeless, 2012).

Although gaps in overall health and achievement between poverty-stricken children and their economically better-off peers are substantial, a considerable number of children from financially stressed families are resilient, faring well. A host of interventions aimed at helping children and youths surmount the risks of poverty exist. Some address family functioning and parenting, while others directly target children's academic, emotional, and social skills. And more programs are recognizing that because poverty-stricken children often experience multiple adversities, they benefit most from efforts that are multifaceted (Kagan, 2013a). We will discuss many such interventions later in this book.

## Affluence

Despite their advanced education and great material wealth, affluent parents—those in prestigious and high-paying occupations—too often fail to engage in family interaction and parenting that promote favorable development. In several studies, researchers tracked the adjustment of youths growing up in wealthy suburbs. By seventh grade, many showed serious problems that worsened in high school (Luthar & Barkin, 2012; Racz, McMahon, & Luthar, 2011). Their school grades were poor, and they were more likely than youths in general to engage in alcohol and drug use, to commit delinquent acts, and to report high levels of anxiety and depression.

Why are so many affluent youths troubled? Compared to their better-adjusted counterparts, poorly adjusted affluent young people report less emotional closeness, less supervision, and fewer serious consequences for misbehaviors from their parents, who lead professionally and socially demanding lives. As a group, wealthy parents are nearly as physically and emotionally unavailable to their youngsters as parents coping with serious financial strain. At the same time, these parents often make excessive demands for achievement and are critical when their children perform less than perfectly (Luthar, Barkin, & Crossman, 2013). Adolescents whose parents value their accomplishments more than their character are more likely to have academic and emotional problems.

For both affluent and low-SES youths, a simple routine—eating dinner with parents—is associated with a reduction in adjustment difficulties, even after many other aspects of parenting are controlled (see Figure 2.6) (Luthar & Latendresse, 2005). Interventions that make wealthy parents aware of the high costs of a competitive lifestyle, weak involvement in children's lives, and unrealistically high expectations are badly needed.

## Beyond the Family: Neighborhoods and Schools

As the concepts of *mesosystem* and *exosystem* in ecological systems theory make clear, connections between family and community are vital for psychological well-being. From our discussion of poverty, perhaps you can see why: In poverty-stricken

**FIGURE 2.6** Relationship of regularly eating dinner with parents to affluent youths' adjustment problems. Compared with sixth graders who often ate dinner with their parents, those who rarely did so were far more likely to display anxiety and depression, delinquency and substance use, and poor school grades, even after many other aspects of parenting were controlled. In this study, frequent family mealtimes also protected low-SES youths from delinquency and substance use and from classroom learning problems. (Based on Luthar & Latendresse, 2005.)

areas, community life is usually disrupted. Families move often, parks and playgrounds are in disarray, and community centers providing organized leisure time activities do not exist. In such neighborhoods, family violence, child abuse and neglect, child and youth internalizing and externalizing difficulties, adult criminal behavior, and depression and declines in cognitive functioning in older adults are especially high (Chen, Howard, & Brooks-Gunn, 2011; Dunn, Schaefer-McDaniel, & Ramsay, 2010; Ingoldsby et al., 2012; Lang et al., 2008). In contrast, strong family ties to the surrounding social context—as indicated by frequent contact with relatives and friends and regular church, synagogue, temple, or mosque attendance—reduce stress and enhance adjustment.

**Neighborhoods.** Let's look closely at the functions of communities in the lives of children and adults by beginning with the neighborhood. What were your childhood experiences like in the yards, streets, parks, and other community settings surrounding your home? How did you spend your time, whom did you get to know, and how important were these moments to you?

Neighborhoods offer resources and social ties that play an important part in children's development. In an experimental study of neighborhood mobility, low-SES families were randomly assigned vouchers to move out of public housing into neighborhoods varying widely in affluence. Compared with their peers who remained in poverty-stricken areas, children and youths who moved into low-poverty neighborhoods and remained

there for several years showed substantially better physical and mental health and school achievement (Goering, 2003; Leventhal & Brooks-Gunn, 2003; Leventhal & Dupéré, 2011). The ability of low-income families to integrate into the social life of their new neighborhoods was key to favorable outcomes.

Neighborhood resources have a greater impact on economically disadvantaged than on well-to-do young people. Higher-SES families depend less on their immediate surroundings for social support, education, and leisure pursuits. They can afford to transport their children to lessons and entertainment and, if necessary, to better-quality schools in distant parts of the community. In low-income neighborhoods, in-school and after-school programs that substitute for lack of other resources by providing art, music, sports, and other enrichment activities are associated with improved academic performance and a reduction in emotional and behavior problems in elementary and middle school (Durlak, Weissberg, & Pachan, 2010; Kataoka & Vandell, 2013; Vandell, Reisner, & Pierce, 2007). Neighborhood organizations, such as religious youth groups and special interest clubs, contribute to favorable development in adolescence, including increased self-confidence, school achievement, and educational aspirations (Barnes et al., 2007).

Yet in dangerous, disorganized neighborhoods, high-quality activities for children and adolescents are scarce. Even when they are available, crime and social disorder limit young people's access, and parents overwhelmed by financial and other stressors are less likely to encourage their children to participate (Dearing et al., 2009). Thus, the neediest children and youths are especially likely to miss out on these development-enhancing activities.

A 5-year-old enjoys working with volunteers at a community garden sponsored by the Boys & Girls Clubs of America. Neighborhood resources are especially important for the development of economically disadvantaged children and youths.

## LOOK and LISTEN

Ask several parents to list their school-age children's regular lessons and other enrichment activities. Then inquire about home and neighborhood factors that either encourage or impede their children's participation.

The Better Beginnings, Better Futures Project of Ontario, Canada, is a government-sponsored set of pilot programs aimed at preventing the dire consequences of neighborhood poverty. The most successful of these efforts, using neighborhood elementary schools as its base, provided children ages 4 to 8 years with in-class, before- and after-school, and summer enrichment activities. Project staff also visited each child's parents regularly, informed them about community resources, and encouraged their involvement in the child's school and neighborhood life. And a community-wide component focused on improving the neighborhood as a place to live, by offering leadership training and adult education programs and organizing safety initiatives and special events and celebrations (Peters, 2005; Peters, Petrunka, & Arnold, 2003). Longitudinal follow-ups as participants reached grades 3, 6, 9, and 12 revealed wide-ranging benefits compared with children and families living in impoverished neighborhoods without this set of programs (Peters et al., 2010; Worton et al., 2014). Among these were gains in children's academic achievement and social adjustment, a reduction in adolescent delinquency, and parent-reported improved family functioning, child-rearing practices, and sense of community connection.

During late adulthood, neighborhoods become increasingly important because people spend more time at home. Despite the availability of planned housing for older adults, about 90 percent remain in regular housing, usually in the same neighborhood where they lived during their working lives (U.S. Census Bureau, 2015d). Proximity to relatives and friends is a significant factor in the decision to move or stay put late in life (Hooymann, Kawamoto, & Kiyak, 2015). In the absence of nearby family members, older adults mention neighbors and nearby friends as resources they rely on most for physical and social support.

**Schools.** Unlike the informal worlds of family and neighborhood, the school is a formal institution designed to transmit knowledge and skills needed to become productive members of society. Children and youths in the developed world spend much time in school—a total of about 14,000 hours, on average, by high school graduation. And today, because many children younger than age 5 attend “school-like” child-care centers or pre-schools, the impact of schooling begins earlier and is even more powerful than these figures suggest.

Schools are complex social systems that affect many aspects of development. Schools differ in their physical environments—student body size, number of children per class, and space available for work and play. They also vary in their educational philosophies—whether teachers regard students as passive

learners to be molded by adult instruction; as active, curious beings who determine their own learning; or as collaborative partners assisted by adult experts, who guide their mastery of new skills. Finally, the social life of schools varies—for example, in the degree to which students cooperate and compete; in the extent to which students of different abilities, SES, and ethnic backgrounds learn together; and in whether they are safe, humane settings or riddled with peer harassment and violence (Evans, 2006). We will discuss each of these aspects of schooling in later chapters.

Achieving well in elementary and secondary school is crucial for admission to and success in college. Beginning in the 1960s, obtaining a college degree became the main route to securing a highly skilled, well-paying job. In addition to elevated job status and lifetime earnings, higher education contributes to life satisfaction and longevity, and among SES variables, it probably does so uniquely. Well-educated adults tend to have larger social networks and, therefore, access to more social support. Education also enhances knowledge and decision-making skills—for example, in the realms of health behavior and family functioning. Increased education is linked to reduced likelihood of smoking, heavy drinking, unsafe driving, and overweight and obesity (Cutler & Lleras-Muney, 2010). Compared to adults with less education, college graduates less often have children out of wedlock and more often have stable marriages (Cancian & Haskins, 2013; Pew Research Center, 2010a).

As with SES and family functioning, the impact of schooling and academic achievement on development and life chances strengthens over time. Furthermore, these contextual factors are interrelated: Children living in low-income and poverty-stricken neighborhoods are more likely to attend underfunded schools and experience poorer quality education. For these reasons, educational interventions aimed at upgrading the educational experiences and school performance of economically disadvantaged children are best begun in the early years (Crosnoe & Benner, 2015). But intervening at later periods to target specific educational problems is also helpful—for example, by providing high-quality vocational education to non-college-bound youths.

Students whose parents are involved in school activities and attend parent–teacher conferences show better academic achievement. Higher-SES parents, whose backgrounds and values are similar to those of teachers, are more likely to maintain regular school contact. In contrast, low-SES and ethnic minority parents often feel uncomfortable about coming to school, and daily stressors reduce the energy they have for school involvement (Grant & Ray, 2010). Teachers and administrators must take extra steps with low-SES and ethnic minority families to build supportive family–school ties.

When these efforts lead to cultures of good parenting and teaching, they deliver an extra boost to student success. For example, students attending schools with many highly involved parents achieve especially well (Darling & Steinberg, 1997). And when excellent education becomes a team effort of teachers, administrators, and community members, its effects on learning are stronger and reach many more students (Hauser-Cram et al., 2006).

## The Cultural Context

Our discussion in Chapter 1 emphasized that human development can be fully understood only when viewed in its larger cultural context. In the following sections, we expand on this theme by taking up the role of the *macrosystem* in development. First, we discuss ways that cultural values and practices affect environmental contexts for development. Then we consider how healthy development depends on laws and government programs that shield people from harm and foster their well-being.

**Cultural Values and Practices.** Cultures shape family interaction and community settings beyond the home—in short, all aspects of daily life. Many of us remain blind to aspects of our own cultural heritage until we see them in relation to the practices of others.

Consider the question, Who should be responsible for rearing young children? How would you answer it? Here are some typical responses from my students: “If parents decide to have a baby, then they should be ready to care for it.” “Most people are not happy about others intruding into family life.” These statements reflect a widely held opinion in the United States—that the care and rearing of children, and paying for that care, are the duty of parents, and only parents. This view has a long history—one in which independence, self-reliance, and the privacy of family life emerged as central American values (Dodge & Haskins, 2015; Halfon & McLearn, 2002). It is one reason, among others, that the public has been slow to endorse government-supported benefits for all families, such as high-quality child care and paid employment leave for meeting family needs. It has also contributed to the large number of U.S. families who remain poor, even though family members are gainfully employed (Gruendel & Aber, 2007; UNICEF, 2013).

Although the culture as a whole may value independence and privacy, not all citizens share the same values. Some belong to **subcultures**—groups of people with beliefs and customs that differ from those of the larger culture. Many ethnic minority groups in the United States have cooperative family structures, which help protect their members from the harmful effects of poverty. As the Cultural Influences box on the following page indicates, the African-American tradition of **extended-family households**, in which parent and child live with one or more adult relatives, is a vital feature of black family life that has promoted resilience in its members, despite a long history of prejudice and economic deprivation.

Active, involved extended families also characterize other minorities, such as Asian, Native-American, and Hispanic subcultures. Within these families, grandparents play meaningful roles in guiding younger generations; adults who face employment, marital, or child-rearing difficulties receive assistance and emotional support; and caregiving is enhanced for children and older adults (Jones & Lindahl, 2011; Mutchler, Baker, & Lee, 2007). In Hispanic extended families, for example, grandparents are even more likely to share in rearing young children than are African-American grandparents—a collaborative parenting

## Cultural Influences

### The African-American Extended Family

The African-American extended family can be traced to the African heritage of most black Americans. In many African societies, newly married couples do not start their own households. Instead, they live with a large extended family, which assists its members with all aspects of daily life. This tradition of maintaining a broad network of kin ties traveled to North America during the period of slavery. Since then, it has served as a protective shield against the destructive impact of poverty and racial prejudice on African-American family life. Today, more black than white adults have relatives other than their own children living in the same household. African-American parents also live closer to kin, often establish family-like relationships with friends and neighbors, see more relatives during the week, and perceive them as more important figures in their lives (Boyd-Franklin, 2006; McAdoo & Younge, 2009).

By providing emotional support and sharing essential resources, the African-American extended family helps reduce the stress of poverty and single parenthood. Extended-family members often help with child rearing, and adolescent mothers living in extended families are more likely to complete high school and get a job than mothers living on their own—factors that benefit children's well-being (Gordon, Chase-Lansdale, & Brooks-Gunn, 2004).

For single mothers rearing children and adolescents, extended-family living continues to be associated with more positive mother-child interaction. Even after establishing their own home, single mothers often invite family members or close friends to live with them. This kinship support increases the likelihood of effective parenting, which is related to gains in children's academic performance and social skills and to reduced antisocial behavior (Taylor, 2010; Washington, Gleeson, & Rulison, 2013).

Finally, the extended family plays an important role in transmitting African-American culture. Compared with nuclear-family households (which include only parents and their children), extended-family arrangements place more emphasis on cooperation and on moral and religious values. And older black adults, such as grandparents and great-grandparents,

view educating children about their African heritage as especially important (Mosely-Howard & Evans, 2000; Taylor, 2000). These influences strengthen family bonds, enhance children's development, and increase the chances that the extended-family lifestyle will carry over to the next generation.

© JANINE WIEDEL PHOTOLIBRARY/ALAMY STOCK PHOTO

Three generations enjoy a family picnic. Strong bonds with extended-family members have helped protect many African-American children against the destructive impact of poverty and racial prejudice.

arrangement that has physical and emotional health benefits for grandparents, parents, and children alike (Goodman & Silverstein, 2006). A likely reason for such far-reaching effects is that intergenerational shared parenting is consistent with the Hispanic cultural ideal of *familism*, which places an especially high priority on close, harmonious family bonds and meeting family needs.

Our discussion so far reflects two broad sets of values on which cultures and subcultures are commonly compared: *collectivism* versus *individualism* (Triandis & Gelfand, 2012). In cultures that emphasize collectivism, people stress group goals over individual goals and value *interdependent* qualities, such as social harmony, obligations and responsibility to others, and col-

laborative endeavors. In cultures that emphasize individualism, people are largely concerned with their own personal needs and value *independence*—personal exploration, discovery, achievement, and choice in relationships. Although it is the most common basis for comparing cultures, the collectivism-individualism distinction is controversial because both sets of values exist, in varying mixtures, in most cultures (Taras et al., 2014). Nevertheless, consistent cross-national differences in collectivism-individualism remain: The United States is more individualistic than most Western European countries, which place greater weight on collectivism. These values affect a nation's approach to protecting the well-being of its children, families, and aging citizens.

**Public Policies and Lifespan Development.** When widespread social problems arise, such as poverty, homelessness, hunger, and disease, nations attempt to solve them through devising **public policies**—laws and government programs designed to improve current conditions. For example, when poverty increases and families become homeless, a country might decide to build more low-cost housing, raise the minimum wage, and increase welfare benefits. When reports indicate that many children are not achieving well in school, federal and state governments might grant more tax money to school districts, strengthen teacher preparation, and make sure that help reaches children who need it most. And when older adults have difficulty making ends meet because of inflation, a nation might increase its social security benefits.

U.S. public policies safeguarding children and youths have lagged behind policies for older adults. And compared with other industrialized nations, both sets of policies have been slow to emerge in the United States.

**Policies for Children, Youths, and Families.** We have already seen that although many U.S. children fare well, a large number grow up in environments that threaten their development. As Table 2.4 reveals, the United States does not rank well on any key measure of children's health and well-being.

The problems of children and youths extend beyond the indicators in the table. The Affordable Care Act, signed into law in 2010, extended government-supported health insurance to all children in low-income families. But expanded coverage for low-income adults, including parents, is not mandatory for the states, leaving 13 percent of adults without an affordable coverage

option. Largely because uninsured parents lack knowledge of how to enroll their children, 11 percent of children eligible for the federally supported Children's Health Insurance Program (CHIP)—more than 5 million—do not receive coverage (Kaiser Family Foundation, 2015). Furthermore, the United States has been slow to move toward national standards and funding for child care. Affordable care is in short supply, and much of it is mediocre to poor in quality (Burchinal et al., 2015; Phillips & Lowenstein, 2011). In families affected by divorce, weak enforcement of child support payments heightens poverty in mother-headed households. And 7 percent of 16- to 24-year-olds who dropped out of high school have not returned to earn a diploma (U.S. Department of Education, 2015).

Why have attempts to help children and youths been difficult to realize in the United States? A complex set of political and economic forces is involved. Cultural values of self-reliance and privacy have made government hesitant to become involved in family matters. Furthermore, good social programs are expensive, and they must compete for a fair share of a country's economic resources. Children can easily remain unrecognized in this process because they cannot vote or speak out to protect their own interests, as adult citizens do (Ripple & Zigler, 2003). They must rely on the goodwill of others to become an important government priority.

**Policies for Older Adults.** Until well into the twentieth century, the United States had few policies in place to protect its aging population. For example, Social Security benefits, which address the income needs of retired citizens who contributed to society through prior employment, were not awarded until the

**TABLE 2.4**  
**How Does the United States Compare to Other Nations on Indicators of Children's Health and Well-Being?**

INDICATOR	U.S. RANK <sup>a</sup>	SOME COUNTRIES THE UNITED STATES TRAILS
Childhood poverty (among 20 industrialized nations considered)	20th	Canada, Germany, Iceland, Ireland, Norway, Sweden, United Kingdom <sup>b</sup>
Infant deaths in the first year of life (among 39 industrialized nations considered)	39th	Canada, Greece, Hungary, Ireland, Singapore, Spain
Teenage birth rate (among 20 industrialized nations considered)	20th	Australia, Canada, Czech Republic, Denmark, Hungary, Iceland, Poland, Slovakia
Public expenditure on education as a percentage of gross domestic product <sup>c</sup> (among 32 industrialized nations considered)	13th	Belgium, France, Iceland, New Zealand, Portugal, Spain, Sweden
Public expenditure on early childhood education as a percentage of gross domestic product <sup>c</sup> (among 34 industrialized nations considered)	21st	Austria, France, Germany, Italy, Netherlands, Sweden
Public expenditure on health as a percentage of total health expenditure, public plus private (among 34 industrialized nations considered)	34th	Australia, Austria, Canada, France, Hungary, Iceland, Switzerland, New Zealand

<sup>a</sup>1 = highest, or best, rank.

<sup>b</sup>The U.S. childhood poverty rate of 21 percent greatly exceeds poverty in these nations, which have standards of living similar to the United States. For example, the childhood poverty rate is 13 percent in Canada, 12 percent in the United Kingdom, 11 percent in Ireland, 7 percent in Sweden, and 6 percent in Norway. Deep poverty affects just 2.5 percent of children in Canada, and a fraction of 1 percent in the other countries just listed. In contrast, 10 percent of U.S. children live in deep poverty.

<sup>c</sup>Gross domestic product is the value of all goods and services produced by a nation during a specified time period. It provides an overall measure of a nation's wealth.

Sources: OECD, 2013a, 2015c; Sedgh et al., 2015; UNICEF, 2013; U.S. Census Bureau, 2015d.

late 1930s. Yet most Western nations had social security systems a decade or more earlier (Karger & Stoesz, 2014). In the 1960s, U.S. federal spending on programs for older adults expanded rapidly. Medicare, a national health insurance program for older people that pays partial health-care costs, was initiated. This leaves about one-third of older adults' health expenditures to be covered by supplemental private insurance, government health insurance for low-income adults, or out-of-pocket payments (Davis, Schoen, & Bandeali, 2015).

Social Security and Medicare consume 97 percent of the U.S. federal budget for older adults. Consequently, U.S. programs have been criticized for neglecting social services. To meet this need, a national network for planning, coordinating, and delivering assistance to older adults has been established. Approximately 655 Area Agencies on Aging operate at regional and local levels, assessing community needs and offering communal and home-delivered meals, self-care education, elder abuse prevention, and a wide range of other social services. But limited funding means that the Area Agencies help far too few people in need.

As noted earlier, many older adults—especially women, ethnic minorities, and those living alone—remain in dire economic straits. Those who had interrupted employment histories, held jobs without benefits, or suffered lifelong poverty are not eligible for Social Security. Although all Americans age 65 and older are guaranteed a minimum income, the guaranteed amount is below the poverty line—the amount judged necessary for bare subsistence by the federal government. Furthermore, Social Security benefits are rarely adequate as a sole source of retirement income; they must be supplemented through other pensions and family savings. But a substantial percentage of U.S. aging citizens do not have access to these resources. Therefore, they are

**FIGURE 2.7** Percentage of older adults living in poverty in 20 industrialized nations. Among the countries listed, the United States has the highest rate of older adults living in poverty. Public expenditures on social security and other income guarantees for this group are far greater in the highly ranked nations than in the United States. (Based on Luxembourg Income Study, 2015.)

more likely than other age groups to be among the “near poor” (U.S. Department of Health and Human Services, 2015e).

Nevertheless, the U.S. aging population is financially much better off now than in the past. Today, older adults are a large, powerful, well-organized constituency, far more likely than children or low-income families to attract the support of politicians. As a result, the number of aging poor has declined from 1 in 3 people in 1960 to just under 1 in 10 today (U.S. Census Bureau, 2015d). Still, as Figure 2.7 shows, aging adults in the United States are less well off than those in many other Western nations, which provide more generous, government-funded income supplements to older adults.

**Looking Toward the Future.** Despite the worrisome state of many children, families, and aging citizens, efforts are being made to improve their condition. Throughout this book, we will discuss many successful programs that could be expanded. Also, growing awareness of the gap between what we know and what we do to better people's lives has led experts in developmental

science to join with concerned citizens as advocates for more effective policies. As a result, several influential interest groups devoted to the well-being of children or older adults have emerged.

In the United States, the Children's Defense Fund (CDF), [www.childrensdefense.org](http://www.childrensdefense.org), is a nonprofit organization that engages in public education and partners with other organizations, communities, and elected officials to improve policies for children. Another energetic advocacy organization is the National Center for Children in Poverty, [www.nccp.org](http://www.nccp.org), dedicated to advancing the economic security, health, and welfare of U.S. children in low-income families by informing policymakers of relevant research.

About half of Americans over age 50, both retired and employed, are members of AARP (originally known as the American Association of Retired Persons), [www.aarp.org](http://www.aarp.org). It has a large and energetic lobbying staff that works for increased government benefits of all kinds for older adults. Among its programs is an effort to mobilize older voters, an initiative that keeps lawmakers highly sensitive to policy proposals affecting aging Americans.

Besides strong advocacy, public policies that enhance development depend on research that documents needs and evaluates programs to spark improvements. Today, more researchers are collaborating with community and government agencies to enhance the social relevance of their investigations. They are also doing a better job of disseminating their findings in easily understandable, compelling ways, through reports to government officials, websites aimed at increasing public understanding, and collaborations with the media to ensure accurate and effective reporting (Shonkoff & Bales, 2011). In these ways, researchers are helping to create the sense of immediacy about the condition of children, families, and older adults that is necessary to spur a society into action.

AARP members sign a petition, to be sent to U.S. Senators, in support of legalizing importation of cheaper prescription medications from Canada. Lobbying for policy change is one way AARP addresses the needs of older adults.

## Ask yourself

**CONNECT** Links between family and community foster development throughout the lifespan. Provide examples and research findings that support this idea.

**APPLY** Check your local newspaper or one or two national news websites to see how often articles appear on the condition of children, families, and older adults. Why is it important for researchers to communicate with the public about the well-being of these sectors of the population?

**REFLECT** Do you agree with the widespread American sentiment that government should not become involved in family life? Explain.

## Understanding the Relationship Between Heredity and Environment

**2.6** Explain the various ways heredity and environment may combine to influence complex traits.

So far in this chapter, we have discussed a wide variety of genetic and environmental influences, each of which has the power to alter the course of development. Yet people who are born into the same family (and who therefore share both genes and environments) are often quite different in characteristics. We also know that some individuals are affected more than others by their homes, neighborhoods, and communities. How do scientists explain the impact of heredity and environment when they seem to work in so many different ways?

**Behavioral genetics** is a field devoted to uncovering the contributions of nature and nurture to this diversity in human traits and abilities. All contemporary researchers agree that both heredity and environment are involved in every aspect of development. But for polygenic traits (those due to many genes) such as intelligence and personality, scientists are a long way from knowing the precise hereditary influences involved. Although they are making progress in identifying variations in DNA sequences associated with complex traits, so far these genetic markers explain only a small amount of variation in human behavior, and a minority of cases of most psychological disorders (Plomin, 2013). For the most part, scientists are still limited to investigating the impact of genes on complex characteristics indirectly.

Some believe that it is useful and possible to answer the question of *how much each factor contributes* to differences among people. A growing consensus, however, regards that question as unanswerable. These investigators believe that heredity and environment are inseparable (Lickliter & Honeycutt, 2015; Moore, 2013). The important question, they maintain, is *how nature and nurture work together*. Let's consider each position in turn.

## The Question, “How Much?”

To infer the role of heredity in complex human characteristics, researchers use special methods, the most common being the *heritability estimate*. Let’s look closely at the information this procedure yields, along with its limitations.

**Heritability.** **Heritability estimates** measure the extent to which individual differences in complex traits in a specific population are due to genetic factors. We will take a brief look at heritability findings on intelligence and personality here, returning to them in greater detail in later chapters. Heritability estimates are obtained from **kinship studies**, which compare the characteristics of family members. The most common type of kinship study compares identical twins, who share all their genes, with fraternal twins, who, on average, share only half. If people who are genetically more alike are also more similar in intelligence and personality, then the researcher assumes that heredity plays an important role.

Kinship studies of intelligence provide some of the most controversial findings in the field of developmental science. Some experts claim a strong genetic influence, whereas others believe that heredity is barely involved. Currently, most kinship findings support a moderate role for heredity. When many twin studies are examined, correlations between the scores of identical twins are consistently higher than those of fraternal twins. In a summary of more than 10,000 twin pairs of diverse ages, the correlation for intelligence was .86 for identical twins and .60 for fraternal twins (Plomin & Spinath, 2004).

Researchers use a complex statistical procedure to compare these correlations, arriving at a heritability estimate ranging from 0 to 1.00. The typical overall value for intelligence is about .50 for twin samples in Western industrialized nations, suggesting that differences in genetic makeup explain half the variation in intelligence. However, heritability increases with age, from approximately .20 in infancy, to .40 in childhood and adolescence, to .60 in adulthood, with some late adulthood estimates as high as .80 (Plomin & Deary, 2015). As we will see later, one explanation is that, compared to children, adults exert greater personal control over their intellectual experiences—for example, how much time they spend reading or solving challenging problems. Adopted children’s mental test scores are more strongly related to their biological parents’ scores than to those of their adoptive parents, offering further support for the role of heredity (Petrill & Deater-Deckard, 2004).

Heritability research also reveals that genetic factors are important in personality. For frequently studied traits, such as sociability, anxiety, agreeableness, and activity level, heritability estimates obtained on child, adolescent, and young adult twins are moderate, in the .40s and .50s (Vukasović & Bratko, 2015). Unlike intelligence, however, heritability of personality does not increase over the lifespan (Loehlin et al., 2005).

Twin studies of schizophrenia, bipolar disorder, and autism generally yield high heritabilities, above .70. Heritabilities for antisocial behavior and major depression are considerably lower, in the .30s and .40s (Ronald & Hoekstra, 2014; Sullivan, Daly, &

O’Donovan, 2012). Again, adoption studies are consistent with these results. Biological relatives of adoptees with schizophrenia, bipolar disorder, or autism are more likely than adoptive relatives to share the same disorder (Plomin, DeFries, & Knopik, 2013).

**Limitations of Heritability.** The accuracy of heritability estimates depends on the extent to which the twin pairs studied reflect genetic and environmental variation in the population. Within a population in which all people have very similar home, school, and community experiences, individual differences in intelligence and personality are assumed to be largely genetic, and heritability estimates should be close to 1.00. Conversely, the more environments vary, the more likely they are to account for individual differences, yielding lower heritability estimates. In twin studies, most twin pairs are reared together under highly similar conditions. Even when separated twins are available for study, social service agencies have often placed them in advantaged homes that are alike in many ways (Richardson & Norgate, 2006). Because the environments of most twin pairs are less diverse than those of the general population, heritability estimates are likely to exaggerate the role of heredity.

Heritability estimates can easily be misapplied. For example, high heritabilities have been used to suggest that ethnic

JANEK SKARZYŃSKI/AFP/GETTY IMAGES

Kasia Ofmanski, of Warsaw, Poland, holds photos of Nina (right), the identical twin from whom she was mistakenly separated at birth, and Edyta (left), who was assumed to be her twin and who grew up with her. When the twins first met at age 17, Kasia exclaimed, “She’s just like me.” They found many similarities: Both were physically active, extroverted, and earned similar grades in school. Clearly heredity contributes to personality traits, but generalizing from twin evidence to the population is controversial.

differences in intelligence, such as the poorer performance of black children compared to white children, have a genetic basis (Jensen, 1969, 2001; Rushton, 2012; Rushton & Jensen, 2006). Yet heritabilities computed on mostly white twin samples do not explain test score differences between ethnic groups. We have already seen that large socioeconomic differences are involved. In Chapter 9, we will discuss research indicating that when black children are adopted into economically advantaged homes at an early age, their scores are well above average and substantially higher than those of children growing up in impoverished families.

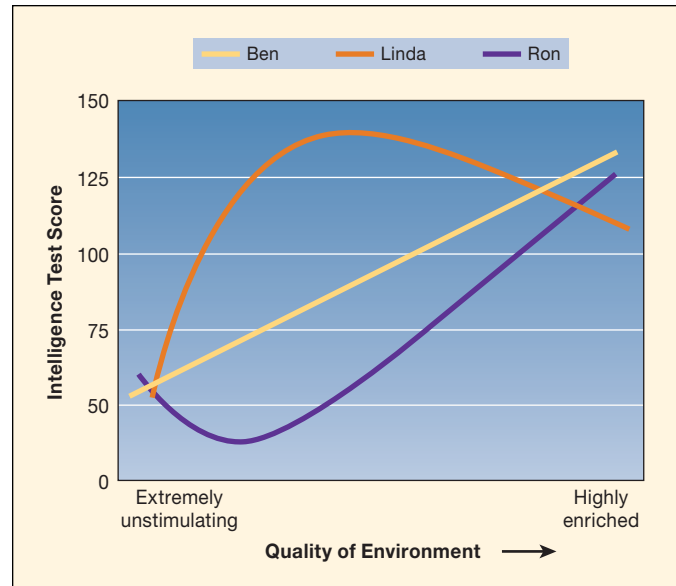

Perhaps the most serious criticism of heritability estimates has to do with their limited usefulness. Though confirming that heredity contributes to a broad array of human traits, these statistics give us no precise information on how intelligence and personality develop or how children might respond to environments designed to help them develop as far as possible (Baltes, Lindenberger, & Staudinger, 2006). Indeed, the heritability of children's intelligence increases as parental education and income increase—that is, as children grow up in conditions that allow them to make the most of their genetic endowment. In impoverished environments, children are prevented from realizing their potential. Consequently, enhancing these children's experiences through interventions—such as parent education and high-quality preschool or child care—has a greater impact on development (Bronfenbrenner & Morris, 2006; Phillips & Lowenstein, 2011).

## The Question, “How?”

Today, most researchers view development as the result of a dynamic interplay between heredity and environment. How do nature and nurture work together? Several concepts shed light on this question.

**Gene–Environment Interaction.** The first of these ideas is **gene–environment interaction**, which means that because of their genetic makeup, individuals differ in their responsiveness to qualities of the environment (Rutter, 2011). Let's explore this idea in Figure 2.8. Gene–environment interaction can apply to any characteristic; here it is illustrated for intelligence. Notice that when environments vary from extremely unstimulating to highly enriched, Ben's intelligence increases steadily, Linda's rises sharply and then falls off, and Ron's begins to increase only after the environment becomes modestly stimulating.

Gene–environment interaction highlights two important points. First, it shows that because each of us has a unique genetic makeup, we respond differently to the same environment. Notice in Figure 2.8 how a poor environment results in similarly low scores for all three individuals. But when the environment provides a moderate level of stimulation, Linda is by far the best-performing child. And in a highly enriched environment, Ben does best, followed by Ron, both of whom now outperform Linda. Second, sometimes different gene–environment combinations can make two people look the same! For example, if Linda is reared in a minimally stimulating environment, her score will

**FIGURE 2.8** Gene–environment interaction, illustrated for intelligence by three children who differ in responsiveness to quality of the environment. As environments vary from extremely unstimulating to highly enriched, Ben's intelligence test score increases steadily, Linda's rises sharply and then falls off, and Ron's begins to increase only after the environment becomes modestly stimulating.

be about 100—average for people in general. Ben and Ron can also obtain this score, but to do so, they must grow up in a fairly enriched home (Gottlieb, Wahlsten, & Lickliter, 2006).

Recently, researchers have made strides in identifying gene–environment interactions in personality development. In Chapter 6 we will see that young children with certain genes that increase their risk of an emotionally reactive temperament respond especially strongly to variations in parenting quality (Bakermans-Kranenburg & van IJzendoorn, 2015). When parenting is favorable, they gain control over their emotions and adjust as well or better than other children. But when parenting is unfavorable, they become increasingly irritable, difficult, and poorly adjusted, more so than children not at genetic risk.

**Gene–Environment Correlation.** A major problem in trying to separate heredity and environment is that they are often correlated (Rutter, 2011; Scarr & McCartney, 1983). According to the concept of **gene–environment correlation**, our genes influence the environments to which we are exposed. The way this happens changes with age.

**Passive and Evocative Correlation.** At younger ages, two types of gene–environment correlation are common. The first is called *passive* correlation because the child has no control over it. Early on, parents provide environments influenced by their own heredity. For example, parents who are good athletes emphasize outdoor activities and enroll their children in swimming and gymnastics. Besides being exposed to an “athletic environment,” the children may have inherited their parents' athletic ability. As a result, they are likely to become good athletes for both genetic and environmental reasons.

**FIGURE 2.9 Similarity in mothers' interactions for pairs of siblings differing in genetic relatedness.** The correlations shown are for maternal negativity. The pattern illustrates evocative gene–environment correlation. Identical twins evoke similar maternal treatment because of their identical heredity. As genetic resemblance between siblings declines, the strength of the correlation drops. Mothers vary their interactions as they respond to each child's unique genetic makeup. (Based on Reiss, 2003.)

The second type of gene–environment correlation is *evocative*. Children evoke responses that are influenced by the child's heredity, and these responses strengthen the child's original style. For example, a cooperative, attentive child probably receives more patient and sensitive interactions from parents than an inattentive, distractible child. In support of this idea, the more genetically alike siblings are, the more their parents treat them alike, in both warmth and negativity. Parents' treatment of identical twins is highly similar, whereas their treatment of fraternal twins and

nontwin biological siblings is only moderately so. And little resemblance exists in parents' warm and negative interactions with unrelated stepsiblings (see Figure 2.9) (Reiss, 2003). Likewise, identical-twin pairs—who resemble each other more in sociability than fraternal twins do—tend to be more alike in the degree of friendliness they evoke from new playmates (DiLalla, Bersted, & John, 2015).

**Active Correlation.** At older ages, *active* gene–environment correlation becomes common. As children extend their experiences beyond the immediate family and are given the freedom to make more choices, they actively seek environments that fit with their genetic tendencies. The well-coordinated, muscular child spends more time at after-school sports, the musically talented child joins the school orchestra and practices his violin, and the intellectually curious child is a familiar patron at her local library.

This tendency to actively choose environments that complement our heredity is called **niche-picking** (Scarr & McCartney, 1983). Infants and young children cannot do much niche-picking because adults select environments for them. In contrast, older children, adolescents, and adults are increasingly in charge of their environments.

Niche-picking explains why pairs of identical twins reared apart during childhood and later reunited may find, to their surprise, that they have similar hobbies, food preferences, and vocations—a trend that is especially marked when twins' environmental opportunities are similar. Niche-picking also helps us understand why identical twins become somewhat more alike, and fraternal twins and adopted siblings less alike, in intelligence with age (Bouchard, 2004). And niche-picking sheds light on why adult identical-twin pairs, compared to fraternal twins and other adults, select more similar spouses and best friends—in height, weight, personality, political attitudes, and other characteristics (Rushton & Bons, 2005).

The influence of heredity and environment is not constant but changes over time. With age, genetic factors may become more important in influencing the environments we experience and choose for ourselves.

© MACDUFF EVERTON/THE IMAGE WORKS

These parents share their enthusiasm for outdoor sports with their children, who may have inherited the parents' athletic ability. When heredity and environment are correlated, the influence of one cannot be separated from the influence of the other.

### Environmental Influences on Gene Expression.

Notice how, in the concepts just considered, heredity is granted priority. In gene–environment interaction, it affects responsiveness to particular environments. Similarly, gene–environment correlation is viewed as driven by genetics, in that children’s genetic makeup causes them to receive, evoke, or seek experiences that actualize their hereditary tendencies (Rutter, 2011).

A growing number of researchers take issue with the supremacy of heredity, arguing that it does not dictate children’s experiences or development in a rigid way. For example, in a large Finnish adoption study, children with a genetic tendency for mental illness (based on having a biological mother diagnosed with schizophrenia) but who were being reared by healthy adoptive parents showed little evidence of mental disturbance—no more than a control group with healthy biological and adoptive parents. In contrast, schizophrenia and other psychological impairments piled up in adoptees whose biological and adoptive parents were both mentally ill (Tienari, Wahlberg, & Wynne, 2006; Tienari et al., 2003).

Furthermore, parents and other caring adults can *uncouple* unfavorable gene–environment correlations by providing children with positive experiences that modify the expression of heredity, yielding favorable outcomes. In a study that tracked the development of 5-year-old identical twins, pair members tended to resemble each other in level of aggression. And the more aggression they displayed, the more maternal anger and criticism they received (a gene–environment correlation). Nevertheless, some mothers treated their twins differently. When followed up at age 7, twins who had been targets of more maternal negativity engaged in even more antisocial behavior. In contrast, their better-treated, genetically identical counterparts showed a reduction in disruptive acts (Caspi et al., 2004). Good parenting protected them from a spiraling, antisocial course of development.

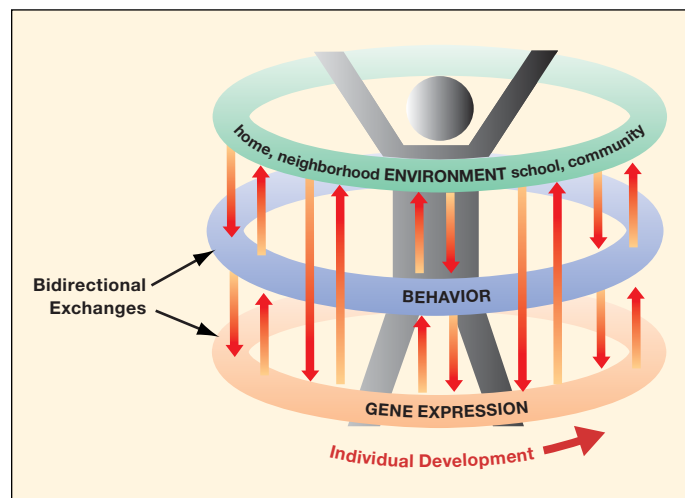

Accumulating evidence reveals that the relationship between heredity and environment is not a one-way street, from genes to environment to behavior. Rather, like other system influences considered in this and the previous chapter, it is *bidirectional*: Genes affect people’s behavior and experiences, but their experiences and behavior also affect gene expression. This view of the relationship between heredity and environment, depicted in Figure 2.10, is called **epigenesis**, which means development resulting from ongoing, bidirectional exchanges between heredity and all levels of the environment (Cox, 2013; Gottlieb, 1998, 2007).

Biologists are beginning to clarify the precise mechanisms through which environment can alter gene expression without changing the DNA sequence—a field of research called *epigenetics*. One such mechanism is **methylation**—a biochemical process triggered by certain experiences, in which a set of chemical compounds (called a methyl group) lands on top of a gene and changes its impact, reducing or silencing its expression. Methylation levels can be measured, and they help explain why identical twins, though precisely the same in DNA sequencing, sometimes display strikingly different phenotypes with age.

A case study of a pair of identical-twin adults offers an illustration. Researchers reported that they had been highly similar in intelligence and personality throughout childhood. But after high school, one twin remained close to home, studied law, married, and had children, whereas the other left home, became a journalist, and traveled to war zones around the world, where she repeatedly encountered life-threatening situations and saw many people killed or wounded. Assessed again in their forties, the twins remained similar in intelligence. But compared with the “law twin,” the “war twin” engaged in more risky behaviors, including drinking and gambling (Kaminsky et al., 2007). DNA analyses revealed greater methylation of a gene known to affect impulse control in the “war twin” than in the “law twin”—a difference much larger than is typical for identical-twin pairs.

Environmental modification of gene expression can occur at any age, even prenatally. One way maternal smoking, and other harmful prenatal environmental factors we will take up in Chapter 3, may compromise development is through altered DNA methylation (Markunas et al., 2014). And as the Biology and Environment box on the following page illustrates, severe maternal stress during pregnancy is linked to long-term impairment in children’s capacity to manage stress, with gene methylation likely contributing to unfavorable outcomes. The harsh conditions associated with chronic poverty, as well, are believed to exert their impact epigenetically, leaving behind a “biological residue” that compromises the child’s potential for a physically and mentally healthy life (Miller et al., 2009). Furthermore, animal evidence indicates that some methylated genes are passed to offspring at conception, thereby affecting development in subsequent generations (Grossniklaus et al., 2013).

We must keep in mind, however, that epigenetic processes also operate positively: Favorable rearing experiences alter gene expression in ways that enhance development! And some negative epigenetic modifications may be reversible through carefully

**FIGURE 2.10 Epigenesis.** Development takes place through ongoing, bidirectional exchanges between heredity and all levels of the environment. Genes affect behavior and experiences. Experiences and behavior also affect gene expression. (Adapted from Gottlieb, 2007.)

## Biology and Environment

### The Tutsi Genocide and Epigenetic Transmission of Maternal Stress to Children

In 1994, in a genocidal rampage committed by members of the Hutu majority against the Tutsi people of Rwanda, nearly 1 million perished within a three-month period. The horror was so extreme that in surveys of Rwandans during the years following the genocide, an estimated 40 to 60 percent reported symptoms of *post-traumatic stress disorder (PTSD)* (Neugebauer et al., 2009; Schaal et al., 2011). In PTSD, flashbacks, nightmares, anxiety, irritability, angry outbursts, and difficulty concentrating lead to intense distress, physical symptoms, and loss of interest in relationships and daily life.

Parental PTSD is a strong predictor of child PTSD (Brand et al., 2011; Yehuda & Bierer, 2009). In both children and adults, PTSD is associated with disruptions in the body's stress response system, reflected in abnormal blood levels of stress hormones. In appropriate concentrations, stress hormones assist our brains in managing stress effectively. In individuals with PTSD, stress hormone levels are either too high or (more often) too low, contributing to persistently disturbed stress regulation.

Mounting evidence confirms that exposure to extreme adversity increases methylation of a chromosome-5 gene called *GR*, which plays a central role in stress-hormone regulation.

Might this epigenetic process contribute to parent-to-child transmission of PTSD?

To explore this question, researchers identified 50 Tutsi women who had been pregnant during the genocide (Perroud et al., 2014). Half had been directly exposed to the trauma; the other half had not been exposed due to being out of the country at the time. Eighteen years later, the mothers and their adolescent children were assessed for PTSD and depression by trained psychologists. Blood samples enabled genetic testing for methylation of the *GR* gene and assessment of stress-hormone levels (which we will discuss further in Chapter 3).

Compared with non-exposed mothers, mothers who witnessed the genocidal carnage had substantially higher PTSD and depression scores, and children of the two groups of mothers differed similarly. Also, as Figure 2.11 reveals, exposed mothers and their children displayed stronger *GR* methylation. And consistent with methylation's dampening effect on gene expression, trauma-exposed mothers and their children had much lower stress-hormone levels than their non-exposed counterparts.

These findings are consistent with other evidence, in both animals and humans, indicating that prenatal exposure to the biological consequences of severe maternal stress can

induce epigenetic changes, through methylation, that impair functioning of the body's stress response system (Daskalakis & Yehuda, 2014; Mueller & Bale, 2008). In the Tutsi mothers and children, the effects of genocidal trauma were long-lasting,

JONATHAN TORGOVNIK/GETTY IMAGES REPORTAGE

This Rwandan mother gave birth shortly after the Tutsi genocide. Nine years later, she continues to suffer from PTSD caused by first-hand experience of atrocities, including repeated rape and loss of her mother, brother, and two sisters in the massacre. Her daughter's PTSD and depression might be the result of prenatal exposure to severe maternal stress, which can trigger epigenetic changes that disrupt the body's stress response system.

evident in serious psychological disorders nearly two decades later.

As the researchers noted, more remains to be discovered about exactly how maternal trauma exposure compromised the Tutsi children's capacity to manage stress. Epigenetic processes, not just prenatally but also at later ages, may have been largely responsible. Alternatively, poor-quality parenting, resulting from maternal anxiety, irritability, anger, and depression, could have been the major influence. More likely, epigenetic changes, inept parenting, and other unfavorable environmental factors combined to place the Tutsi children at high risk for PTSD and depression. In Chapter 3, we will return to the impact of prenatal stress, including evidence showing that its negative impact can be lessened or prevented through social support.

**FIGURE 2.11** Methylation status of the *GR* gene in trauma-exposed and non-trauma-exposed Tutsi mothers and their children. Mothers who had been directly exposed to the Rwandan Tutsi genocide, as well as their children, showed elevated methylation of the *GR* gene, which is centrally involved in functioning of the body's stress response system. (Based on Perroud et al., 2014.)

designed interventions (van IJzendoorn, Bakermans-Kranenburg, & Ebstein, 2011). The concept of epigenesis reminds us that the genome is not static but is constantly in flux, both reflecting and affecting the individual's ever-changing environment.

Epigenetics is still an emerging field, and clarifying its mechanisms may prove to be even more complex than efforts to understand DNA sequence variations (Duncan, Pollastri, & Smoller, 2014). But from what we already know, one lesson is clear: Development is best understood as a series of complex exchanges between nature and nurture. Although people cannot be changed in any way we might desire, environments can modify genetic influences. The success of any attempt to improve development depends on the characteristics we want to change, the genetic makeup of the individual, and the type and timing of our intervention.

## Ask yourself

**CONNECT** Explain how each of the following concepts supports the conclusion that genetic influences on human characteristics are not constant but change over time: somatic mutation (page 49), niche-picking (page 69), and epigenesis (page 70).

**APPLY** Bianca's parents are accomplished musicians. At age 4, Bianca began taking piano lessons. By age 10, she was accompanying the school choir. At age 14, she asked to attend a special music high school. Explain how gene–environment correlation promoted Bianca's talent.

**REFLECT** What aspects of your own development—for example, interests, hobbies, college major, or vocational choice—are probably due to niche-picking? Explain.

## Summary / chapter 2

### Genetic Foundations (p. 44)

#### 2.1 What are genes, and how are they transmitted from one generation to the next?

- Each individual's **phenotype**, or directly observable characteristics, is a product of both **genotype** and environment. **Chromosomes**, rodlike structures within the cell nucleus, contain our hereditary endowment. Along their length are **genes**, segments of **deoxyribonucleic acid (DNA)**. **Protein-coding genes** send instructions for making proteins to the cell's cytoplasm; **regulator genes** modify those instructions. A wide range of environmental factors also alter gene expression.
- Gametes**, or sex cells, result from a cell division process called **meiosis**, which halves the number of chromosomes. In meiosis, genes shuffle to create new combinations, ensuring that each individual receives a unique set from each parent. Once sperm and ovum unite, the resulting **zygote** will then have the full complement of chromosomes.
- If the fertilizing sperm carries an X chromosome, the child will be a girl; if it contains a Y chromosome, a boy. **Fraternal**, or **dizygotic**, **twins** result when two ova are released from the mother's ovaries and each is fertilized. **Identical**, or **monozygotic**, **twins** develop when a zygote divides in two during the early stages of cell duplication.

© RAY EVANS/ALAMY STOCK PHOTO

#### 2.2 Describe various patterns of gene–gene interaction.

- Traits controlled by single genes follow **dominant–recessive** and **incomplete-dominance** patterns of inheritance. **Homozygous** individuals have two identical **alleles**, or forms of a gene. **Heterozygous** individuals, with one dominant and one recessive allele, are **carriers** of the recessive trait. In **incomplete dominance**, both alleles are expressed in the phenotype.
- X-linked inheritance** applies when recessive disorders are carried on the X chromosome and, therefore, are more likely to affect males. In **genomic imprinting**, one parent's allele is activated, regardless of its makeup.
- Harmful genes arise from **mutation**, which can occur spontaneously or be caused by hazardous environmental agents. Germline mutation occurs in the cells that give rise to gametes; somatic mutation can occur in body cells at any time of life.

- Human traits that vary on a continuum, such as intelligence and personality, result from **polygenic inheritance**—the effects of many genes.

#### 2.3 Describe major chromosomal abnormalities, and explain how they occur.

- Most chromosomal abnormalities result from errors during meiosis. The most common, Down syndrome, leads to physical defects and intellectual disability. **Sex chromosome** disorders are milder than defects of the **autosomes** and usually cause very specific cognitive impairments.

### Reproductive Choices (p. 51)

#### 2.4 What procedures can assist prospective parents in having healthy children?

- Genetic counseling** helps couples at risk for giving birth to children with genetic abnormalities consider reproductive options. **Prenatal diagnostic methods** allow early detection of developmental problems. Genetic engineering and gene therapy offer hope for treating hereditary disorders.
- Reproductive technologies, such as donor insemination, in vitro fertilization, and surrogate motherhood, enable individuals to become parents who otherwise would not, but they raise legal and ethical concerns.

- Many adults who cannot conceive or are likely to transmit a genetic disorder choose adoption. Although adopted children have more learning and emotional problems than children in general, most fare well in the long run. Warm, sensitive parenting predicts favorable development.

## Environmental Contexts for Development (p. 56)

### 2.5 Describe family functioning from the perspective of ecological systems theory, along with aspects of the environment that support family well-being and development.

- The first and foremost context for development is the family, a dynamic system characterized by bidirectional influences, in which each member's behaviors affect those of others. Both direct and indirect influences operate within the family system, which must continually adjust to new events and changes in its members. Warm, gratifying family ties, which foster effective **coparenting**, help ensure children's psychological health.
- **Socioeconomic status (SES)** profoundly affects family functioning. Higher-SES families tend to be smaller, to emphasize psychological traits, and to engage in warm, verbally stimulating interaction with children. Lower-SES families often stress external characteristics and use more commands, criticism, and physical punishment.

- Children's development in affluent families may be impaired by parents' physical and emotional unavailability. Poverty and homelessness can seriously undermine development.
- Supportive ties between family and community are vital for psychological well-being. Stable, socially cohesive neighborhoods that provide constructive leisure and enrichment activities promote favorable development in both children and adults. High-quality schooling and academic achievement profoundly affect life chances, with their impact strengthening over time.
- The values and practices of cultures and **subcultures** affect all aspects of daily life. **Extended-family households**, which are common among many ethnic minority groups, help protect family members from the negative effects of poverty and other stressful life conditions.
- Consistent cross-national differences in **collectivism–individualism** powerfully affect approaches to devising **public policies** to address social problems. Largely because of its strongly individualistic values, the United States lags behind other developed nations in policies safeguarding children and families, as well as older adults.

DAVID EDWARDS/NATIONAL GEOGRAPHIC/GETTY IMAGES

JANEK SKARZYNSKI/AFP/GETTY IMAGES

- In **gene–environment interaction**, heredity influences each individual's unique response to qualities of the environment. **Gene–environment correlation** and **niche-picking** describe how genes affect the environments to which individuals are exposed.
- **Epigenesis** reminds us that development is best understood as a series of complex exchanges between heredity and all levels of the environment. Epigenetic research is uncovering biochemical processes—such as **methylation**—through which environment can modify gene expression.

## Adjusting to the New Family Unit

One fall, Yolanda and Jay enrolled in an evening section of my child development course, when Yolanda was just two months pregnant. In their early thirties, married for several years, and with their careers well under way, they had decided to have a baby. Each week, they arrived for class full of questions: “How does the baby grow before birth?” “When is each organ formed?” “Has its heart begun to beat?” “Can it hear, feel, or sense our presence?”

Most of all, Yolanda and Jay wanted to do everything possible to make sure their baby would be born healthy. Yolanda started to wonder about her diet and whether she should keep up her daily aerobic workout. And she asked me whether an aspirin for a headache, a glass of wine at dinner, or a few cups of coffee during the workday might be harmful.

In this chapter, we answer Yolanda and Jay's questions, along with a great many more that scientists have asked about the events before birth. First, we trace prenatal development, paying special attention to supports for healthy growth as well as damaging influences that threaten the child's health and survival. Because the changes taking place during these

nine months are so astounding, the prenatal environment can exert a powerful, lasting impact—for better or for worse—on physical and mental health.

Next, we turn to the events of childbirth. Today, women in industrialized nations have many choices about where and how they give birth, and hospitals go to great lengths to make the arrival of a new baby a rewarding, family-centered event.

Yolanda and Jay's son Joshua reaped the benefits of his parents' careful attention to his needs during pregnancy: He was strong, alert, and healthy at birth. Nevertheless, the birth process does not always go smoothly. We will consider the pros and cons of medical interventions, such as pain-relieving drugs and surgical deliveries, designed to ease a difficult birth and protect the health of mother and baby. Our discussion also addresses the development of infants born underweight or too early. We conclude with a close look at the remarkable capacities of newborns. ●

## Prenatal Development

**3.1** List the three periods of prenatal development, and describe the major milestones of each.

The sperm and ovum that unite to form the new individual are uniquely suited for the task of reproduction. The ovum is a tiny sphere, measuring  $\frac{1}{175}$  inch in diameter—barely visible to the naked eye as a dot the size of the period at the end of this sentence. But in its microscopic world, it is a giant—the largest cell in the human body. The ovum’s size makes it a perfect target for the much smaller sperm, which measure only  $\frac{1}{500}$  inch.

### Conception

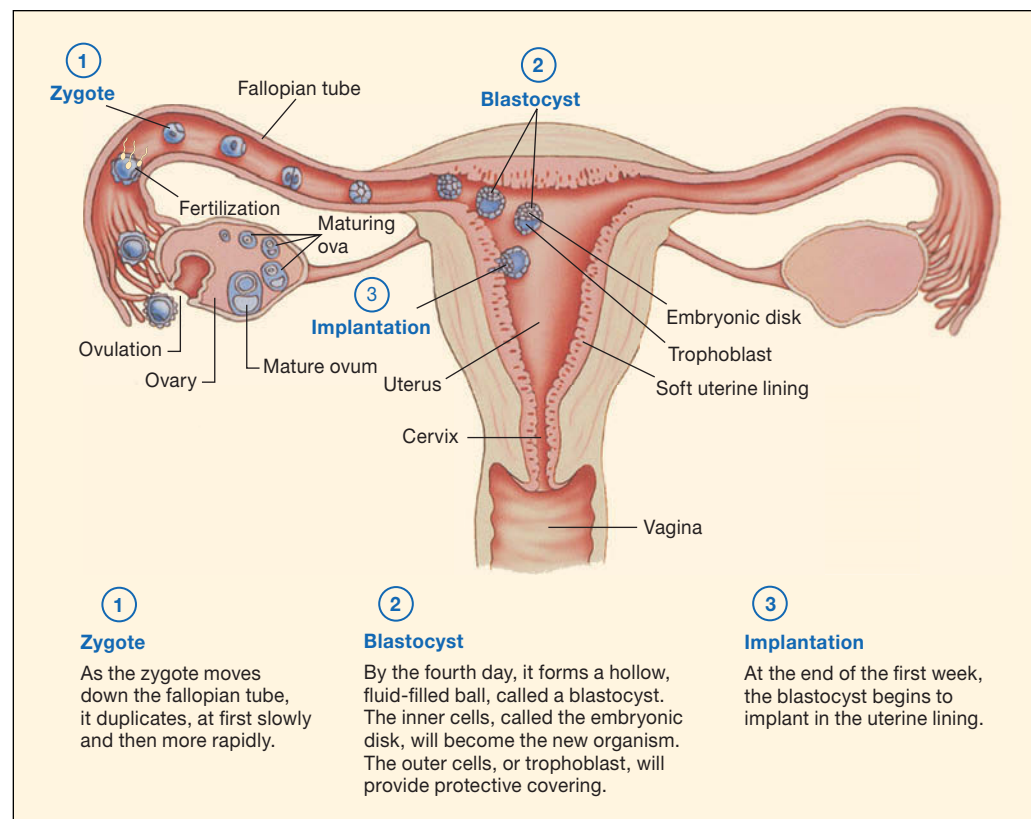

About once every 28 days, in the middle of a woman’s menstrual cycle, an ovum bursts from one of her *ovaries*, two walnut-sized organs located deep inside her abdomen, and is drawn into one of two *fallopian tubes*—long, thin structures that lead to the hollow, softly lined uterus (see Figure 3.1). While the ovum is traveling, the spot on the ovary from which it was released, now called the *corpus luteum*, secretes hormones that prepare the lining of the uterus to receive a fertilized ovum. If pregnancy does not occur, the corpus luteum shrinks, and the lining of the uterus is discarded two weeks later with menstruation.

The male produces sperm in vast numbers—an average of 300 million a day—in the *testes*, two glands located in the *scrotum*, sacs that lie just behind the penis. In the final process of maturation, each sperm develops a tail that permits it to swim long distances, upstream in the female reproductive tract, through the *cervix* (opening of the uterus) and into the fallopian tube, where fertilization usually takes place. The journey is difficult, and many sperm die. Only 300 to 500 reach the ovum, if one happens to be present. Once in the fallopian tube, sperm live for up to six days and can lie in wait for the ovum, which survives for only one day after its release from the ovary. However, most conceptions result from intercourse occurring during a three-day period—on the day of ovulation or during the two days preceding it (Mu & Fehring, 2014).

With conception, the story of prenatal development begins to unfold. The vast changes that take place during the 38 weeks of pregnancy are usually divided into three periods: (1) the germinal period, (2) the period of the embryo, and (3) the period of the fetus. As we look at what happens in each, you may find it useful to refer to Table 3.1, which summarizes milestones of prenatal development.

### Germinal Period

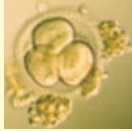

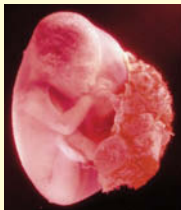

The germinal period lasts about two weeks, from fertilization and formation of the zygote until the tiny mass of cells drifts down and out of the fallopian tube and attaches itself to the wall

**FIGURE 3.1** Female reproductive organs, showing fertilization, early cell duplication, and implantation.

**TABLE 3.1**  
Milestones of Prenatal Development

TRIMESTER	PRENATAL PERIOD	WEEKS	LENGTH AND WEIGHT	MAJOR EVENTS
First	Germinal 	1		The one-celled zygote multiplies and forms a blastocyst.
		2		The blastocyst burrows into the uterine lining. Structures that feed and protect the developing organism begin to form— <i>amnion</i> , <i>chorion</i> , <i>yolk sac</i> , <i>placenta</i> , and <i>umbilical cord</i> .
	Embryo 	3–4	¼ inch (6 mm)	A primitive brain and spinal cord appear. Heart, muscles, ribs, backbone, and digestive tract begin to develop.
		5–8	1 inch (2.5 cm); ½ ounce (4 g)	Many external body structures (face, arms, legs, toes, fingers) and internal organs form, and production and migration of neurons in the brain begin. The sense of touch starts to develop, and the embryo can move.
	Fetus 	9–12	3 inches (7.6 cm); less than 1 ounce (28 g)	Rapid increase in size begins. Nervous system, organs, and muscles become organized and connected, touch sensitivity extends to most of the body, and new behavioral capacities (kicking, thumb sucking, mouth opening, and rehearsal of breathing) appear. External genitals are well-formed, and the fetus's sex is evident.
Second		13–24	12 inches (30 cm); 1.8 pounds (820 g)	The fetus continues to enlarge rapidly. In the middle of this period, the mother can feel fetal movements. Vernix and lanugo keep the fetus's skin from chapping in the amniotic fluid. Most of the brain's neurons are in place by 24 weeks. Eyes are sensitive to light, and the fetus reacts to sound.
Third		25–38	20 inches (50 cm); 7.5 pounds (3,400 g)	The fetus has a good chance of survival if born during this time. Size increases. Lungs mature. Rapid brain development, in neural connectivity and organization, enables sensory and behavioral capacities to expand. In the middle of this period, a layer of fat is added under the skin. Antibodies are transmitted from mother to fetus to protect against disease. Most fetuses rotate into an upside-down position in preparation for birth.

of the uterus. The zygote's first cell duplication is long and drawn out; it is not complete until about 30 hours after conception. Gradually, new cells are added at a faster rate. By the fourth day, 60 to 70 cells exist that form a hollow, fluid-filled ball called a *blastocyst* (refer again to Figure 3.1). The cells on the inside of the blastocyst, called the *embryonic disk*, will become the new organism; the outer ring of cells, termed the *trophoblast*, will become the structures that provide protective covering and nourishment.

**Implantation.** Between the seventh and ninth days, **implantation** occurs: The blastocyst burrows deep into the uterine

lining. Surrounded by the woman's nourishing blood, it starts to grow in earnest. At first, the trophoblast (protective outer layer) multiplies fastest. It forms a membrane, called the **amnion**, that encloses the developing organism in *amniotic fluid*, which helps keep the temperature of the prenatal world constant and provides a cushion against any jolts caused by the woman's movement. A *yolk sac* emerges that produces blood cells until the developing liver, spleen, and bone marrow are mature enough to take over this function (Moore, Persaud, & Torchia, 2016a).

The events of these first two weeks are delicate and uncertain. As many as 30 percent of zygotes do not survive this period. In some, the sperm and ovum did not join properly. In others, cell

© LENNART NILSSON, A CHILD IS BORN/TT NYHETSBYRÅN

**Germinal period: seventh to ninth day.** The fertilized ovum duplicates rapidly, forming a hollow ball of cells, or blastocyst, by the fourth day after fertilization. Here the blastocyst, magnified thousands of times, burrows into the uterine lining between the seventh and ninth days.

duplication never begins. By preventing implantation in these cases, nature eliminates most prenatal abnormalities (Sadler, 2014).

**The Placenta and Umbilical Cord.** By the end of the second week, cells of the trophoblast form another protective membrane—the **chorion**, which surrounds the amnion. From the chorion, tiny fingerlike *villi*, or blood vessels, emerge.<sup>1</sup> As these villi burrow into the uterine wall, the placenta starts to develop. By bringing the embryo's and mother's blood close together, the **placenta** permits food and oxygen to reach the developing organism and waste products to be carried away. A membrane forms that allows these substances to be exchanged but prevents the mother's and embryo's blood from mixing directly.

The placenta is connected to the developing organism by the **umbilical cord**, which first appears as a primitive body stalk and, during the course of pregnancy, grows to a length of 1 to 3 feet. The umbilical cord contains one large vein that delivers blood loaded with nutrients and two arteries that remove waste products. The force of blood flowing through the cord keeps it firm, so it seldom tangles while the embryo, like a space-walking astronaut, floats freely in its fluid-filled chamber (Moore, Persaud, & Torchia, 2016a).

<sup>1</sup>Recall from Table 2.3 on page 54 that *chorionic villus sampling* is the prenatal diagnostic method that can be performed earliest, at nine weeks after conception.

By the end of the germinal period, the developing organism has found food and shelter. These dramatic beginnings take place before most mothers know they are pregnant.

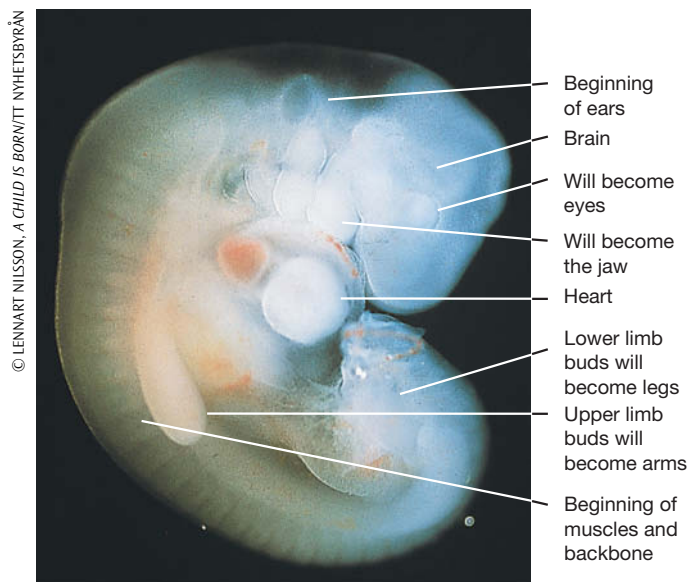

## Period of the Embryo

The period of the **embryo** lasts from implantation through the eighth week of pregnancy. During these brief six weeks, the most rapid prenatal changes take place as the groundwork is laid for all body structures and internal organs.

**Last Half of the First Month.** In the first week of this period, the embryonic disk forms three layers of cells: (1) the *ectoderm*, which will become the nervous system and skin; (2) the *mesoderm*, from which will develop the muscles, skeleton, circulatory system, and other internal organs; and (3) the *endoderm*, which will become the digestive system, lungs, urinary tract, and glands. These three layers give rise to all parts of the body.

At first, the nervous system develops fastest. The ectoderm folds over to form the **neural tube**, or primitive spinal cord. At 3½ weeks, the top swells to form the brain. While the nervous system is developing, the heart begins to pump blood, and muscles, backbone, ribs, and digestive tract appear. At the end of the first month, the curled embryo—only ¼ inch long—consists of millions of organized groups of cells with specific functions.

**The Second Month.** In the second month, growth continues rapidly. The eyes, ears, nose, jaw, and neck form. Tiny buds become arms, legs, fingers, and toes. Internal organs are more distinct: The intestines grow, the heart develops separate chambers, and the liver and spleen take over production of blood cells so that the yolk sac is no longer needed. Changing body proportions cause the embryo's posture to become more upright.

© LENNART NILSSON, A CHILD IS BORN/TT NYHETSBYRÅN

**Period of the embryo: fourth week.** This 4-week-old embryo is only ¼-inch long, but many body structures have begun to form.

© LENNART NILSSON, A CHILD IS BORN/TIT NYHETSBYRÅN

**Period of the embryo: seventh week.** The embryo's posture is more upright. Body structures—eyes, nose, arms, legs, and internal organs—are more distinct. The embryo now responds to touch and can also move, although at less than one inch long and an ounce in weight, it is still too tiny to be felt by the mother.

During the fifth week, production of *neurons* (nerve cells that store and transmit information) begins deep inside the neural tube at the astounding pace of more than 250,000 per minute (Jabès & Nelson, 2014). Once formed, neurons begin traveling along tiny threads to their permanent locations, where they will form the major parts of the brain.

By the end of this period, the embryo—about 1 inch long and  $\frac{1}{2}$  ounce in weight—can already sense its world. It responds to touch, particularly in the mouth area and on the soles of the feet. And it can move, although its tiny flutters are still too light to be felt by the mother (Moore, Persaud, & Torchia, 2016a).

## Period of the Fetus

The period of the **fetus**, from the ninth week to the end of pregnancy, is the longest prenatal period. During this “growth and finishing” phase, the organism increases rapidly in size.

**The Third Month.** In the third month, the organs, muscles, and nervous system start to become organized and connected. Touch sensitivity extends to most of the body (Hepper, 2015). When the brain signals, the fetus kicks, bends its arms, forms a fist, curls its toes, turns its head, opens its mouth, and even sucks its thumb, stretches, and yawns. The tiny lungs begin to expand and contract in an early rehearsal of breathing movements.

© LENNART NILSSON, A CHILD IS BORN/TIT NYHETSBYRÅN

**Period of the fetus: eleventh week.** The fetus grows rapidly. At 11 weeks, the brain and muscles are better connected. The fetus can kick, bend its arms, open and close its hands and mouth, and suck its thumb. Notice the yolk sac, which shrinks as the internal organs take over its function of producing blood cells.

By the twelfth week, the external genitals are well-formed, and the sex of the fetus can be detected with ultrasound (Sadler, 2014). Other finishing touches appear, such as fingernails, toenails, tooth buds, and eyelids. The heartbeat can now be heard through a stethoscope.

Prenatal development is sometimes divided into **trimesters**, or three equal time periods. At the end of the third month, the *first trimester* is complete.

**The Second Trimester.** By the middle of the second trimester, between 17 and 20 weeks, the new being has grown large enough that the mother can feel its movements. Already, the fetus is remarkably active—in motion nearly 30 percent of the time—which helps strengthen the joints and muscles (DiPietro et al., 2015). A white, cheeselike substance called **vernix** emerges on the skin, protecting it from chapping during the long months spent bathing in the amniotic fluid. White, downy hair called **lanugo** also appears over the entire body, helping the vernix stick to the skin.

At the end of the second trimester, many organs are well-developed. And most of the brain's billions of neurons are in place; few will be produced after this time. However, *glial cells*, which support and feed the neurons, continue to increase rapidly throughout the remaining months of pregnancy, as well as after birth. Consequently, brain weight increases tenfold from the twentieth week until birth (Roelfsema et al., 2004). At the same time, neurons begin forming *synapses*, or connections, at a rapid pace.

Brain growth means new sensory and behavioral capacities. The 20-week-old fetus can be stimulated as well as irritated by sounds. And if a doctor looks inside the uterus using fetoscopy (see Table 2.3 on page 54), fetuses try to shield their eyes from the light with their hands, indicating that sight has begun to emerge (Moore, Persaud, & Torchia, 2016a). Still, a fetus born at this time cannot survive. Its lungs are immature, and the brain cannot yet control breathing movements or body temperature.

**The Third Trimester.** During the final trimester, a fetus born early has a chance for survival. The point at which the baby can first survive, called the **age of viability**, occurs sometime between 22 and 26 weeks (Moore, Persaud, & Torchia, 2016a). A baby born between the seventh and eighth months, however, usually needs oxygen assistance to breathe. Although the brain's respiratory center is now mature, tiny air sacs in the lungs are not yet ready to inflate and exchange carbon dioxide for oxygen.

The brain continues to make great strides. The *cerebral cortex*, the seat of human intelligence, enlarges. As rapid gains in neural connectivity and organization continue, the fetus spends more time awake. At 20 weeks, fetal heart rate reveals no periods of alertness. But by 28 weeks, fetuses are awake about 11 percent of the time, a figure that rises to 16 percent just before

birth (DiPietro et al., 1996). Between 30 and 34 weeks, fetuses show rhythmic alternations between sleep and wakefulness that gradually increase in organization (Rivkees, 2003). Around 36 weeks, synchrony between fetal heart rate and motor activity peaks: A rise in heart rate is usually followed within five seconds by a burst of motor activity (DiPietro et al., 2006, 2015). These are clear signs that coordinated neural networks are beginning to form in the brain.

By the end of pregnancy, the fetus takes on the beginnings of a personality. Fetal activity is linked to infant temperament. In one study, more active fetuses during the third trimester became 1-year-olds who could better handle frustration and 2-year-olds who were more active as well as less fearful, in that they more readily interacted with toys and with an unfamiliar adult in a laboratory (DiPietro et al., 2002). Perhaps fetal activity is an indicator of healthy neurological development, which fosters adaptability in childhood. The relationships just described, however, are modest. As we will see in Chapter 6, sensitive caregiving can modify the temperaments of children who have difficulty adapting to new experiences.

The third trimester brings greater responsiveness to external stimulation. As we will see when we discuss newborn capacities, fetuses acquire taste and odor preferences from bathing in

© LENNART NILSSON, A CHILD IS BORN/ITT NYHETSBYRÅN

**Period of the fetus: twenty-second week.** This fetus is almost one foot long and weighs slightly more than one pound. Its movements can be felt easily by the mother and by other family members who place a hand on her abdomen. If born now, the fetus has a slim chance of survival.

© LENNART NILSSON, A CHILD IS BORN/ITT NYHETSBYRÅN

**Period of the fetus: thirty-sixth week.** This fetus fills the uterus. To nourish it, the umbilical cord and placenta have grown large. Notice the vernix (a cheeselike substance) on the skin, which protects it from chapping. The fetus has accumulated fat to aid temperature regulation after birth. In two more weeks, it will be full-term.

and swallowing amniotic fluid (its makeup is influenced by the mother's diet). Between 23 and 30 weeks, connections form between the cerebral cortex and brain regions involved in pain sensitivity. By this time, painkillers should be used in any surgical procedures (Lee et al., 2005). Around 28 weeks, fetuses blink their eyes in reaction to nearby sounds (Saffran, Werker, & Werner, 2006). And around 30 weeks, fetuses presented with a repeated auditory stimulus against the mother's abdomen initially react with a rise in heart rate, electrical brain-wave recordings, and body movements. Then responsiveness gradually declines, indicating *habituation* (adaptation) to the sound. If a new auditory stimulus is introduced, heart rate and brain waves recover to a high level, revealing that the fetus recognizes the new sound as distinct from the original stimulus (Hepper, Dornan, & Lynch, 2012; Muenssinger et al., 2013). This indicates that fetuses can remember for at least a brief period.

Within the next six weeks, fetuses distinguish the tone and rhythm of different voices and sounds—learning that will serve as a springboard for language development. They show systematic heart-rate and brain-wave changes in response to the mother's voice versus the father's or a stranger's, to their native language (English) versus a foreign language (Mandarin Chinese), and to a simple familiar melody (descending tones) versus an unfamiliar melody (ascending tones) (Granier-Deferre et al., 2003; Kisilevsky & Hains, 2011; Kisilevsky et al., 2009; Lecanuet et al., 1993; Lee & Kisilevsky, 2013; Voegtline et al., 2013). And in one clever study, mothers read aloud Dr. Seuss's lively book *The Cat in the Hat* each day during the last six weeks of pregnancy. After birth, their infants learned to turn on recordings of the mother's voice by sucking on nipples (DeCasper & Spence, 1986). They sucked hardest to hear *The Cat in the Hat*—the sound they had come to know while still in the womb.

In the final three months, the fetus gains more than 5 pounds and grows 7 inches. In the eighth month, lanugo typically is shed. A layer of fat is added to assist with temperature regulation. The fetus also receives antibodies from the mother's blood that protect against illnesses, since the newborn's immune system will not work well until several months after birth. In the last weeks, most fetuses assume an upside-down position, partly because of the shape of the uterus and partly because the head is heavier than the feet. Growth slows, and birth is about to take place.

## Ask yourself

**CONNECT** How is brain development related to fetal capacities and behavior? What implications do individual differences in fetal behavior have for infant temperament after birth?

**APPLY** Amy, two months pregnant, wonders how the embryo is being fed and what parts of the body have formed. "I don't look pregnant yet, so does that mean not much development has taken place?" she asks. How would you respond to Amy?

## Prenatal Environmental Influences

**3.2** Cite factors that influence the impact of teratogens, and discuss evidence on the impact of known or suspected teratogens.

**3.3** Describe the impact of additional maternal factors on prenatal development.

**3.4** Why is early and regular health care vital during the prenatal period?

Although the prenatal environment is far more constant than the world outside the womb, many factors can affect the embryo and fetus. Yolanda and Jay learned that parents—and society as a whole—can do a great deal to create a safe environment for development before birth.

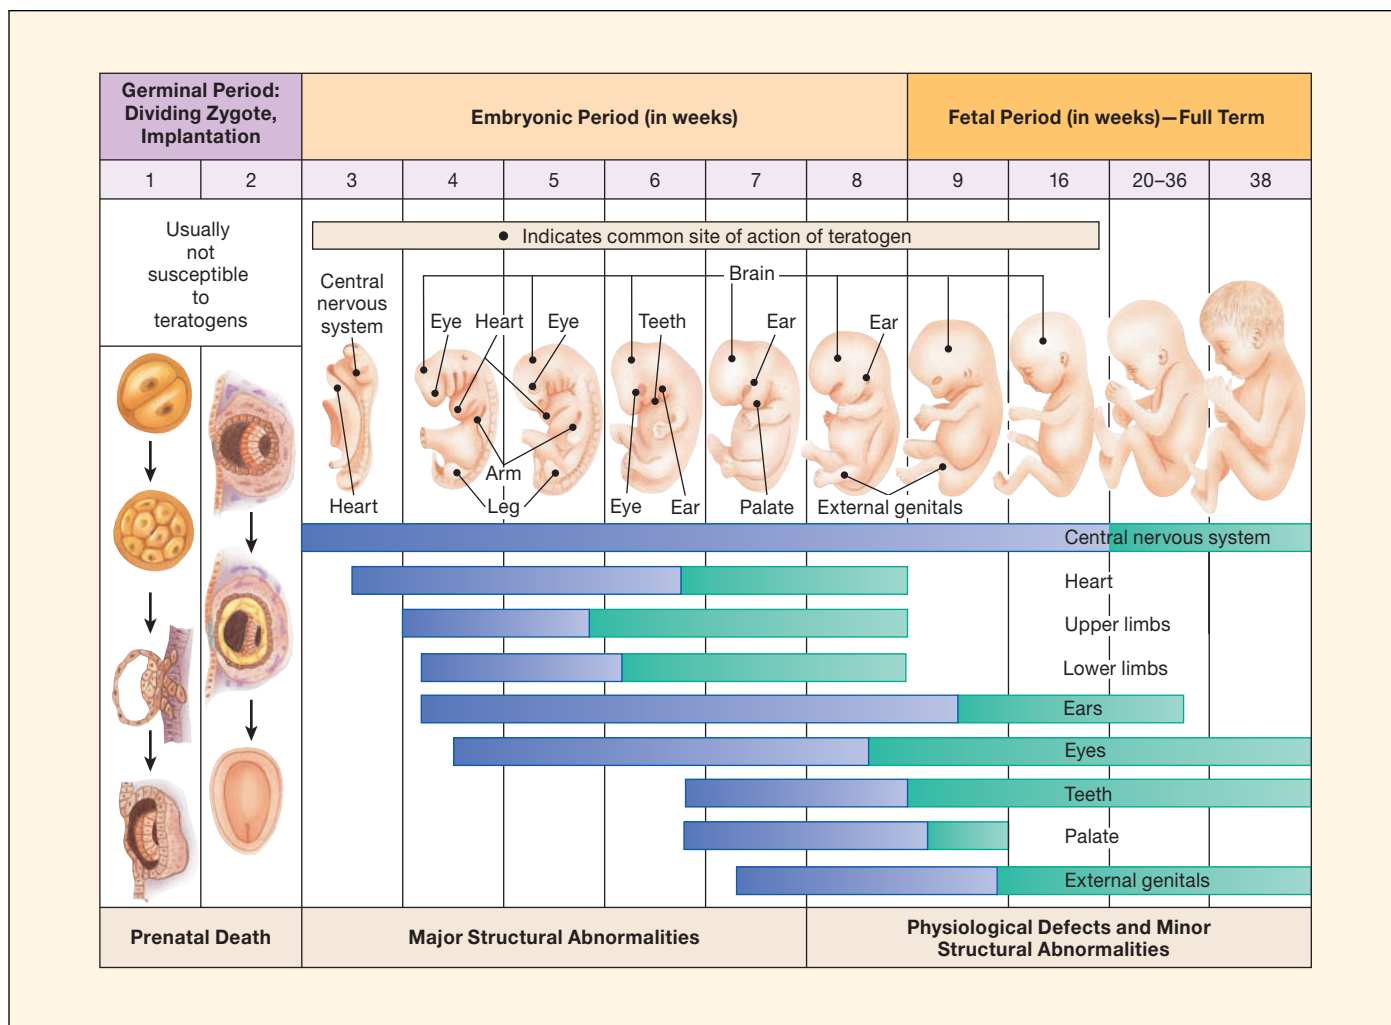

## Teratogens

The term **teratogen** refers to any environmental agent that causes damage during the prenatal period. Scientists chose this label (from the Greek word *teras*, meaning “malformation” or “monstrosity”) because they first learned about harmful prenatal influences from cases in which babies had been profoundly damaged. But the harm done by teratogens is not always straightforward. It depends on the following factors:

- **Dose.** As we discuss particular teratogens, you will see that larger doses over longer time periods usually have more negative effects.
- **Heredity.** The genetic makeup of the mother and the developing organism plays an important role. Some individuals are better able than others to withstand harmful environments.
- **Other negative influences.** The presence of several negative factors at once, such as additional teratogens, poor nutrition, and lack of medical care, can worsen the impact of a harmful agent.
- **Age.** The effects of teratogens vary with the age of the organism at time of exposure. To understand this last idea, think of the *sensitive period* concept introduced in Chapter 1. A sensitive period is a limited time span in which a part of the body or a behavior is biologically prepared to develop rapidly. During that time, it is especially sensitive to its surroundings. If the environment is harmful, then damage occurs, and recovery is difficult and sometimes impossible.

Figure 3.2 on page 82 summarizes prenatal sensitive periods. In the *germinal period*, before implantation, teratogens rarely have any impact. If they do, the tiny mass of cells is usually so damaged that it dies. The *embryonic period* is the time when serious defects are most likely to occur because the foundations for all body parts are being laid down. During the *fetal period*, teratogenic damage is usually minor. However, organs such as the brain, ears, eyes, teeth, and genitals can still be strongly affected.

**FIGURE 3.2 Sensitive periods in prenatal development.** Each organ or structure has a sensitive period, during which its development may be disturbed. Blue horizontal bars indicate highly sensitive periods. Green horizontal bars indicate periods that are somewhat less sensitive to teratogens, although damage can occur. (Based on *Before We Are Born*, 9th ed., by K. L. Moore, T. V. N. Persaud, & M. G. Torchia, p. 313. Copyright © 2016 Elsevier, Inc.)

The effects of teratogens go beyond immediate physical damage. Some health effects are delayed and may not show up for decades. Furthermore, psychological consequences may occur indirectly, as a result of physical damage. For example, a defect resulting from drugs the mother took during pregnancy can affect others’ reactions to the child as well as the child’s ability to explore the environment. Over time, parent–child interaction, peer relations, and cognitive, emotional, and social development may suffer. Furthermore, prenatally exposed children may be less resilient in the face of environmental risks, such as single parenthood, parental emotional disturbance, or maladaptive parenting (Yumoto, Jacobson, & Jacobson, 2008). As a result, their long-term adjustment may be compromised.

Notice how an important idea about development discussed in earlier chapters is at work here: *bidirectional influences* between child and environment. Now let’s look at what scientists have discovered about a variety of teratogens.

**Prescription and Nonprescription Drugs.** In the early 1960s, the world learned a tragic lesson about drugs and prenatal development. At that time, a sedative called *thalidomide* was widely available in Canada, Europe, and South America. When taken by mothers 4 to 6 weeks after conception, thalidomide produced gross deformities of the embryo’s developing arms and legs and, less frequently, damage to the ears, heart, kidneys, and genitals. About 7,000 infants worldwide were affected (Moore, Persaud, & Torchia, 2016a). As children exposed to thalidomide grew older, many scored below average in intelligence. Perhaps the drug damaged the central nervous system directly. Or the child-rearing conditions of these severely deformed youngsters may have impaired their intellectual development.

Another medication, a synthetic hormone called *diethylstilbestrol (DES)*, was widely prescribed between 1945 and 1970 to prevent miscarriages. As daughters of these mothers reached adolescence and young adulthood, they showed unusually high

rates of cancer of the vagina, malformations of the uterus, and infertility. When they tried to have children, their pregnancies more often resulted in prematurity, low birth weight, and miscarriage than those of non-DES-exposed women. Young men showed an increased risk of genital abnormalities and cancer of the testes (Goodman, Schorge, & Greene, 2011; Reed & Fenton, 2013).

Currently, the most widely used potent teratogen is a vitamin A derivative called *isotretinoin*, prescribed to treat severe acne and taken by hundreds of thousands of women of childbearing age in industrialized nations. Exposure during the first trimester results in eye, ear, skull, brain, heart, and immune system abnormalities (Yook et al., 2012). U.S. regulations for prescribing isotretinoin require female users to commit to avoiding pregnancy by using two methods of birth control.

Indeed, any drug with a molecule small enough to penetrate the placental barrier can enter the embryonic or fetal bloodstream. Yet many pregnant women continue to take over-the-counter medications without consulting their doctors. Aspirin is one of the most common. Some research suggests that aspirin use is linked to brain damage leading to impaired motor control, inattention, and overactivity, though other research fails to confirm these findings (Barr et al., 1990; Kozer et al., 2003; Thompson et al., 2014; Tyler et al., 2012). Coffee, tea, cola, and cocoa contain another frequently consumed drug, caffeine. High doses increase the risk of low birth weight (Sengpiel et al., 2013). Persistent intake of antidepressant medication is associated with an elevated incidence of premature delivery, low birth weight, respiratory distress at birth, and delayed motor development, but contrary evidence exists (Grigoriadis et al., 2013; Huang et al., 2014; Robinson, 2015).

Because children's lives are involved, we must take findings like these seriously. At the same time, we cannot be sure that these frequently used drugs actually cause the problems just mentioned. Often mothers take more than one drug. If the embryo or fetus is injured, it is hard to tell which drug might be responsible or whether other factors correlated with drug taking are at fault. Until we have more information, the safest course of action is the one Yolanda took: Avoid drugs as far as possible.

Unfortunately, many women do not know that they are pregnant during the early weeks of the embryonic period, when exposure to medications (and other teratogens) can be of greatest threat. In some instances, such as antidepressant use by severely depressed mothers, the benefits of drug treatment may outweigh its risks.

**Illegal Drugs.** The use of highly addictive mood-altering drugs, such as cocaine and heroin, has become more widespread, especially in poverty-stricken inner-city areas, where these drugs provide a temporary escape from a daily life of hopelessness. Nearly 6 percent of U.S. pregnant women take these substances (Substance Abuse and Mental Health Services Administration, 2014).

Babies born to users of cocaine, heroin, or methadone (a less addictive drug used to wean people away from heroin) are at risk for a wide variety of problems, including prematurity, low birth

weight, brain abnormalities, physical defects, breathing difficulties, and death around the time of birth (Bandstra et al., 2010; Behnke & Smith, 2013). In addition, these infants are born drug-addicted. They are often feverish and irritable and have trouble sleeping, and their cries are abnormally shrill and piercing—a common symptom among stressed newborns (Barthell & Mrozek, 2013). When mothers with many problems of their own must care for these babies, who are difficult to calm down, cuddle, and feed, behavior problems are likely to persist.

Throughout the first year, heroin- and methadone-exposed infants are less attentive to the environment than nonexposed babies, and their motor development is slow. After infancy, some children get better, while others remain jittery and inattentive (Hans & Jeremy, 2001). The kind of parenting they receive may explain why problems persist for some but not for others.

Evidence on cocaine suggests that some prenatally exposed babies develop lasting difficulties. Cocaine constricts the blood vessels, causing oxygen delivered to the developing organism to fall for 15 minutes following a high dose. It also can alter the production of neurons, formation of synaptic connections, and chemical balance in the fetus's brain. These effects may contribute to an array of cocaine-associated physical malformations, especially of the central nervous system and heart; brain hemorrhages and seizures; and growth retardation (Cain, Bornick, & Whiteman, 2013; Li et al., 2013). Several studies report perceptual, motor, attention, memory, language, and impulse-control problems that persist into adolescence (Bandstra et al., 2011; Coyle, 2013; Singer et al., 2015).

Other investigations, however, reveal no major negative effects of prenatal cocaine exposure (Ackerman, Riggins, & Black, 2010; Buckingham-Howes et al., 2013). These contradictory

This infant, born many weeks before his due date, breathes with the aid of a respirator. Prematurity and low birth weight can result from a variety of environmental influences during pregnancy, including maternal drug and tobacco use.

findings illustrate how difficult it is to isolate the precise damage caused by illegal drugs. Cocaine users vary greatly in the amount, potency, and purity of the cocaine they ingest. Also, they often take several drugs, display other high-risk behaviors, suffer from poverty and other stresses, and engage in insensitive caregiving—factors that worsen outcomes for children (Molnar et al., 2014). But researchers have yet to determine exactly what accounts for findings of cocaine-related damage in some studies but not in others.

Another drug, marijuana, has been legalized for medical and recreational use in some U.S. states. Researchers have linked prenatal marijuana exposure to attention, memory, and academic achievement difficulties; impulsivity and overactivity; and depression as well as anger and aggression in childhood and adolescence (Behnke & Smith, 2013; Goldschmidt et al., 2004; Gray et al., 2005; Jutras-Aswad et al., 2009). As with heroin and cocaine, however, lasting consequences are not well-established. Overall, the effects of illegal drugs are far less consistent than the impact of two legal substances to which we now turn: tobacco and alcohol.

**Tobacco.** Although smoking has declined in Western nations, about 11 percent of U.S. women smoke during their pregnancies (Centers for Disease Control and Prevention, 2015n). The best-known effect of smoking during the prenatal period is low birth weight. But the likelihood of other serious consequences, such as miscarriage, prematurity, cleft lip and palate, blood vessel abnormalities, impaired heart rate and breathing during sleep, infant death, and asthma and cancer later in childhood, also increases (Geerts et al., 2012; Havstad et al., 2012; Howell, Coles, & Kable, 2008; Mossey et al., 2009). The more cigarettes a mother smokes, the greater the chances that her baby will be affected. If a pregnant woman stops smoking at any time, even during the third trimester, she reduces the likelihood that her infant will be born underweight and suffer from future problems (Polakowski, Akinbami, & Mendola, 2009). The earlier she stops, the more beneficial the effects.

Even when a baby of a smoking mother appears to be born in good physical condition, slight behavioral abnormalities may threaten the child's development. Newborns of smoking mothers are less attentive to sounds, display more muscle tension, are more excitable when touched and visually stimulated, and more often have colic (persistent crying). These findings suggest subtle negative effects on brain development (Espy et al., 2011; Law et al., 2003). Consistent with this view, prenatally exposed children and adolescents tend to have shorter attention spans, difficulties with impulsivity and overactivity, poorer memories, lower intelligence and achievement test scores, and higher levels of disruptive, aggressive behavior (Espy et al., 2011; Thakur et al., 2013).

Exactly how can smoking harm the fetus? Nicotine, the addictive substance in tobacco, constricts blood vessels, lessens blood flow to the uterus, and causes the placenta to grow abnormally. This reduces the transfer of nutrients, so the fetus gains

weight poorly. Also, nicotine raises the concentration of carbon monoxide in the bloodstreams of both mother and fetus. Carbon monoxide displaces oxygen from red blood cells, damaging the central nervous system and slowing fetal body growth (Behnke & Smith, 2013). Other toxic chemicals in tobacco, such as cyanide and cadmium, contribute to its damaging effects.

From one-third to one-half of nonsmoking pregnant women are “passive smokers” because their husbands, relatives, or co-workers use cigarettes. Passive smoking is also related to low birth weight, infant death, childhood respiratory illnesses, and possible long-term attention, learning, and behavior problems (Best, 2009; Hawsawi, Bryant, & Goodfellow, 2015). Clearly, expectant mothers should avoid smoke-filled environments.

**Alcohol.** In his moving book *The Broken Cord*, Michael Dorris (1989), a Dartmouth College anthropology professor, described what it was like to rear his adopted son Adam, whose biological mother drank heavily throughout pregnancy and died of alcohol poisoning shortly after his birth. A Sioux Indian, Adam was born with **fetal alcohol spectrum disorder (FASD)**, a term that encompasses a range of physical, mental, and behavioral outcomes caused by prenatal alcohol exposure. Children with FASD are given one of three diagnoses, which vary in severity:

- 1. Fetal alcohol syndrome (FAS)**, distinguished by (a) slow physical growth, (b) a pattern of three facial abnormalities (short eyelid openings; a thin upper lip; a smooth or flattened philtrum, or indentation running from the bottom of the nose to the center of the upper lip), and (c) brain injury, evident in a small head and impairment in at least three areas of functioning—for example, memory, language and communication, attention span and activity level (overactivity), planning and reasoning, motor coordination, or social skills. Other defects—of the eyes, ears, nose, throat, heart, genitals, urinary tract, or immune system—may also be present. Adam was diagnosed as having FAS. As is typical for this disorder, his mother drank heavily throughout pregnancy.
- 2. Partial fetal alcohol syndrome (p-FAS)**, characterized by (a) two of the three facial abnormalities just mentioned and (b) brain injury, again evident in at least three areas of impaired functioning. Mothers of children with p-FAS generally drank alcohol in smaller quantities, and children's defects vary with the timing and length of alcohol exposure. Furthermore, recent evidence suggests that paternal alcohol use around the time of conception can alter gene expression, thereby contributing to symptoms (Alati et al., 2013; Ouko et al., 2009).
- 3. Alcohol-related neurodevelopmental disorder (ARND)**, in which at least three areas of mental functioning are impaired, despite typical physical growth and absence of facial abnormalities. Again, prenatal alcohol exposure, though confirmed, is less pervasive than in FAS (Mattson, Crocker, & Nguyen, 2012).

*Left photo:* This 5-year-old's mother drank heavily during pregnancy. The child's widely spaced eyes, thin upper lip, and flattened philtrum are typical of fetal alcohol syndrome (FAS). *Right photo:* This 12-year-old has the small head and facial abnormalities of FAS. She also shows the cognitive impairments and slow growth that accompany the disorder.

Even when provided with enriched diets, FAS babies fail to catch up in physical size during infancy or childhood. Mental impairment associated with all three FASD diagnoses is also permanent: In his teens and twenties, Adam had trouble concentrating and keeping a routine job, and he suffered from poor judgment. For example, he would buy something and not wait for change or would wander off in the middle of a task. He died at age 23, after being hit by a car.

The more alcohol a woman consumes during pregnancy, the poorer the child's motor coordination, speed of information processing, reasoning, and intelligence and achievement test scores during the preschool and school years (Burden, Jacobson, & Jacobson, 2005; Mattson, Calarco, & Lang, 2006). In adolescence and early adulthood, FASD is associated with persisting attention and motor-coordination deficits, poor school performance, trouble with the law, inappropriate social and sexual behaviors, alcohol and drug abuse, and lasting mental health problems, including depression and high emotional reactivity to stress (Bertrand & Dang, 2012; Hellems et al., 2010; Roszel, 2015).

How does alcohol produce its devastating effects? First, it interferes with production and migration of neurons in the primitive neural tube. Brain-imaging research reveals reduced brain size, damage to many brain structures, and abnormalities in brain functioning, including electrical and chemical activity involved in transferring messages from one part of the brain to another (de la Monte & Kril, 2014; Memo et al., 2013). Second, animal research reveals widespread epigenetic changes in response to alcohol consumption, including altered methylation of many genes, that contribute to deficits in brain functioning (Kleiber et al., 2014). Third, the body uses large quantities of oxygen

to metabolize alcohol. A pregnant woman's heavy drinking draws away oxygen that the developing organism needs for cell growth.

About 25 percent of U.S. mothers report drinking at some time during their pregnancies. As with heroin and cocaine, alcohol abuse is higher in poverty-stricken women. It is especially high among Native Americans, for whom the risk of a baby born with FAS is 20 to 25 times greater than for the rest of the U.S. population (Rentner, Dixon, & Lengel, 2012). Unfortunately, when affected girls later become pregnant, the poor judgment caused by the syndrome often prevents them from understanding why they themselves should avoid alcohol. Thus, the tragic cycle is likely to be repeated in the next generation.

How much alcohol is safe during pregnancy? Even mild drinking, less than one drink per day, is associated with reduced head size (a measure of brain development), slow body growth, and behavior problems (Flak et al., 2014; Martinez-Frias et al., 2004). Recall that other factors—both genetic and environmental—can make some fetuses more vulnerable to teratogens. Therefore, no amount of alcohol is safe. Couples planning a pregnancy and expectant mothers should avoid alcohol entirely.

**Radiation.** Defects due to ionizing radiation were tragically apparent in children born to pregnant women who survived the bombing of Hiroshima and Nagasaki during World War II. Similar abnormalities surfaced in the nine months following the 1986 Chernobyl, Ukraine, nuclear power plant accident. After each disaster, the incidence of miscarriage and babies born with brain damage, physical deformities, and slow physical growth rose dramatically (Double et al., 2011; Schull, 2003). Evacuation of residents in areas near the Japanese nuclear facility damaged by the March 2011 earthquake and tsunami was intended to prevent these devastating outcomes.

Even when a radiation-exposed baby seems normal, problems may appear later. For example, even low-level radiation, resulting from industrial leakage or medical X-rays, can increase the risk of childhood cancer (Fushiki, 2013). In middle childhood, prenatally exposed Chernobyl children had abnormal brain-wave activity, lower intelligence test scores, and rates of language and emotional disorders two to three times greater than those of nonexposed children in the surrounding area. Furthermore, the more tension parents reported, due to forced evacuation from their homes and worries about living in irradiated areas, the poorer their children's emotional functioning (Loganovskaja & Loganovsky, 1999; Loganovsky et al., 2008).

Stressful rearing conditions seemed to combine with the damaging effects of prenatal radiation to impair children's development.

**Environmental Pollution.** In industrialized nations, an astounding number of potentially dangerous chemicals are released into the environment, and many new pollutants are introduced each year. When 10 newborns were randomly selected from U.S. hospitals for analysis of umbilical cord blood, researchers uncovered a startling array of industrial contaminants—287 in all (Houlihan et al., 2005). They concluded that many babies are “born polluted” by chemicals that not only impair prenatal development but increase the chances of life-threatening diseases and health problems later on.

Certain pollutants cause severe prenatal damage. In the 1950s, an industrial plant released waste containing high levels of *mercury* into a bay providing seafood and water for the town of Minamata, Japan. Many children born at the time displayed physical deformities, intellectual disability, abnormal speech, difficulty in chewing and swallowing, and uncoordinated movements. High levels of prenatal mercury exposure disrupt production and migration of neurons, causing widespread brain damage (Caserta et al., 2013; Hubbs-Tait et al., 2005). Prenatal mercury exposure from maternal seafood diets predicts deficits in speed of cognitive processing, attention, and memory during the school years (Boucher et al., 2010, 2012; Lam et al., 2013). Pregnant women are wise to avoid eating long-lived predatory fish, such as swordfish, albacore tuna, and shark, which are heavily contaminated with mercury.

For many years, *polychlorinated biphenyls (PCBs)* were used to insulate electrical equipment, until research showed that, like mercury, they entered waterways and the food supply. In Taiwan, prenatal exposure to high levels of PCBs in rice oil resulted in low birth weight, discolored skin, deformities of the gums and nails, brain-wave abnormalities, and delayed cognitive development (Chen & Hsu, 1994; Chen et al., 1994). Steady, low-level PCB exposure is also harmful. Women who frequently ate PCB-contaminated fish, compared with those who ate little or no fish, had infants with lower birth weights, smaller heads, persisting attention and memory difficulties, and lower intelligence test scores in childhood (Boucher, Muckle, & Bastien, 2009; Polanska, Jurewicz, & Hanke, 2013; Stewart et al., 2008).

Another teratogen, *lead*, is present in paint flaking off the walls of old buildings and in certain materials used in industrial occupations. High levels of prenatal lead exposure are related to prematurity, low birth weight, brain damage, and a wide variety of physical defects. Even at low levels, affected infants and children show slightly poorer mental and motor development (Caserta et al., 2013; Jedrychowski et al., 2009).

Prenatal exposure to *dioxins*—toxic compounds resulting from incineration—is linked to thyroid abnormalities in infancy and to an increased incidence of breast and uterine cancers in women, perhaps through altering hormone levels (ten Tusscher & Koppe, 2004). Even tiny amounts of dioxin in the paternal

This pregnant woman wears a face mask as protection against Singapore's smog, which occasionally hits life-threatening levels. Prolonged exposure to polluted air poses serious risks to prenatal development.

bloodstream cause a dramatic change in the sex ratio of offspring: Affected men father nearly twice as many girls as boys (Ishihara et al., 2007). Dioxin seems to impair the fertility of Y-bearing sperm prior to conception.

Finally, persistent air pollution inflicts substantial prenatal harm. Exposure to traffic-related fumes and smog is associated with reduced infant head size, low birth weight, elevated infant death rates, impaired lung and immune-system functioning, and later respiratory illnesses (Proietti et al., 2013; Ritz et al., 2014).

**Infectious Disease.** About 5 percent of women in industrialized nations catch an infectious disease while pregnant. Although most of these illnesses, such as the common cold, seem to have no impact, a few—as Table 3.2 illustrates—can cause extensive damage.

**Viruses.** In the mid-1960s, a worldwide epidemic of *rubella* (three-day, or German, measles) led to the birth of more than 20,000 American babies with serious defects and to 13,000 fetal and newborn deaths. Consistent with the sensitive period concept, the greatest damage occurs when rubella strikes during the embryonic period. More than 50 percent of infants whose mothers become ill during that time show deafness; eye

deformities, including cataracts; heart, genital, urinary, intestinal, bone, and dental defects; and intellectual disability. Infection during the fetal period is less harmful, but low birth weight, hearing loss, and bone defects may still occur. The organ damage inflicted by prenatal rubella often leads to lifelong health problems, including severe mental illness, diabetes, cardiovascular disease, and thyroid and immune-system dysfunction in adulthood (Duszak, 2009; Waldorf & McAdams, 2013). Routine vaccination in infancy and childhood has made new rubella outbreaks unlikely in industrialized nations. But over 100,000 cases of prenatal infection continue to occur each year, primarily in developing countries in Africa and Asia with weak or absent immunization programs (World Health Organization, 2015e).

The *human immunodeficiency virus (HIV)*, which can lead to *acquired immune deficiency syndrome (AIDS)*, a disease that destroys the immune system, has infected increasing numbers of women over the past three decades. In developing countries, where 95 percent of new infections occur, more than half affect women. In South Africa, for example, 30 percent of all pregnant women are HIV-positive (South Africa Department of Health, 2013). Untreated HIV-infected expectant mothers pass the deadly virus to the developing organism 10 to 20 percent of the time.

© REUTERS/GRANT NEUENBERG/LANDOV

Babies are tested for the HIV virus in a clinic in Mozambique, Africa. Prenatal treatment with antiretroviral drugs reduces transmission of AIDS from mother to child to less than 1 to 2 percent.

AIDS progresses rapidly in infants. By 6 months, weight loss, diarrhea, and repeated respiratory illnesses are common. The virus also causes brain damage, as indicated by seizures, gradual loss in brain weight, and delayed cognitive and motor development. Most untreated prenatal AIDS babies die by age 3 (Siberry, 2015). Antiretroviral drug therapy reduces prenatal transmission to less than 1 to 2 percent, with no harmful consequences to the fetus. These medications have led to a dramatic decline in prenatally acquired HIV in Western nations. Recently, several babies born with HIV for whom aggressive retroviral treatment began within 2 days after birth appeared free of the disease (McNeil, 2014). Although distribution is increasing, antiretroviral drugs remain unavailable to at least one-third of HIV-infected pregnant women in developing countries (World Health Organization, 2015a).

As Table 3.2 reveals, the developing organism is especially sensitive to the family of herpes viruses, for which no vaccine or treatment exists. Among these, *cytomegalovirus* (the most frequent prenatal infection, transmitted through respiratory or sexual contact) and *herpes simplex 2* (which is sexually transmitted) are especially dangerous. In both, the virus invades the mother's genital tract, infecting babies either during pregnancy or at birth.

**Bacterial and Parasitic Diseases.** Table 3.2 also includes several bacterial and parasitic diseases. Among the most common is *toxoplasmosis*, caused by a parasite found in many animals. Pregnant women may become infected from handling contaminated soil while gardening, having contact with the feces of infected cats, or eating raw or undercooked meat or unwashed fruits and vegetables. About 40 percent of women who have the disease transmit it to the developing organism. If it strikes during the first trimester, it is likely to cause eye and brain damage. Later infection is linked to mild visual and cognitive impairments (Wallon et al., 2013). Expectant mothers can avoid toxoplasmosis by making sure that the meat they eat is well-cooked, having pet cats checked for the disease, and turning over the care of litter boxes and the garden to other family members.

## Other Maternal Factors

Besides avoiding teratogens, expectant parents can support prenatal development in other ways. In healthy, physically fit women, regular moderate to vigorous exercise, including walking, swimming, biking, or an aerobic workout, is related to improved fetal cardiovascular functioning, higher birth weight, and a reduction in risk of certain complications, such as pregnancy-induced maternal diabetes and premature birth (Artal, 2015; Jukic et al., 2012). Most women, however, do not engage in sufficient exercise during pregnancy to promote their own and their baby's health. An expectant mother who remains fit experiences fewer physical discomforts in the final weeks.

In the following sections, we examine other maternal factors—nutrition, emotional stress, blood type, and age.

**Nutrition.** During the prenatal period, when children are growing more rapidly than at any other time, they depend totally on the mother for nutrients. A healthy diet that results in a weight gain of 25 to 30 pounds (10 to 13.5 kilograms) helps ensure the health of mother and baby.

Prenatal malnutrition can cause serious damage to the central nervous system. The poorer the mother's diet, the greater the loss in brain weight, especially if malnutrition occurred during the last trimester. During that time, the brain is increasing rapidly in size, and a maternal diet high in all the basic nutrients is necessary for it to reach its full potential. An inadequate diet during pregnancy can also distort the structure of the liver, kidney, pancreas, and other organs, predisposing the individual to later disease. As Figure 3.3 illustrates, large-scale studies reveal a consistent link between low birth weight and high blood pressure, cardiovascular disease, and diabetes in adulthood, even after many other prenatal and postnatal health risks were controlled (Johnson & Schoeni, 2011).

Because poor nutrition suppresses development of the immune system, prenatally malnourished babies frequently catch respiratory illnesses. In addition, they are often irritable and unresponsive to stimulation. In poverty-stricken families, these effects quickly combine with a stressful home life. With age, delays in motor, attention, and memory development, low intelligence test scores, and serious learning problems become more apparent (Monk, Georgieff, & Osterholm, 2013).

Many studies show that providing pregnant women with an adequate quantity of food has a substantial impact on the health of their newborn babies. Vitamin–mineral enrichment is also crucial. For example, taking a folic acid supplement around the

**FIGURE 3.3 Relationship of low birth weight to disease risk in adulthood.** In a follow-up of more than 2,000 U.S. births at age 50, low birth weight was associated with a greatly increased incidence of high blood pressure, heart disease, stroke, and diabetes after many other prenatal and postnatal health risks were controlled. (Based on Johnson & Schoeni, 2011.)

time of conception reduces by more than 70 percent abnormalities of the neural tube, such as *anencephaly* and *spina bifida* (see Table 2.3 on page 54). Folic acid supplementation early in pregnancy also lessens the risk of other physical defects, including cleft lip and palate, circulatory system and urinary tract abnormalities, and limb deformities. Furthermore, adequate folic acid intake during the last 10 weeks of pregnancy cuts in half premature delivery and low birth weight (Goh & Koren, 2008; Hovdenak & Haram, 2012).

Because of these findings, U.S. government guidelines recommend that all women of childbearing age consume 0.4 milligram of folic acid per day (Talaoukar & Arulkumaran, 2011). Because many U.S. pregnancies are unplanned, government regulations mandate that bread, flour, rice, pasta, and other grain products be fortified with folic acid.

Although prenatal malnutrition is highest in poverty-stricken regions of the world, it is not limited to developing countries. The U.S. Special Supplemental Food Program for Women, Infants, and Children (WIC), which provides food packages and nutrition education to low-income pregnant women, reaches about 90 percent of those who qualify because of their extremely low incomes (U.S. Department of Agriculture, 2015b). But many U.S. women who need nutrition intervention are not eligible for WIC.

**Emotional Stress.** When women experience severe emotional stress during pregnancy, their babies are at risk for a wide variety of difficulties. Intense anxiety—especially during the first two trimesters—is associated with higher rates of miscarriage, prematurity, low birth weight, infant respiratory and digestive illnesses, colic (persistent infant crying), sleep disturbances, and irritability during the child’s first three years (Dunkel-Shetter & Lobel, 2012; Field, 2011; Lazinski, Shea, & Steiner, 2008). Prenatal stressors consistently found to impair later physical and psychological well-being include chronic strain due to poverty; major negative life events such as divorce or death of a family member; disasters such as earthquakes or terrorist attacks; and fears specific to pregnancy and childbirth, including persistent anxiety about the health and survival of the baby and oneself. It is important to note that mild to moderate occasional stress has no adverse impact.

How can severe maternal stress affect the developing organism? To understand this process, list changes you sensed in your own body the last time you were under substantial stress. When we experience fear and anxiety, stress hormones released into our bloodstream—such as *epinephrine* (adrenaline) and *cortisol*, known as the “flight or fight” hormones—cause us to be “poised for action.” Large amounts of blood are sent to parts of the body involved in the defensive response—the brain, the heart, and the muscles in the arms, legs, and trunk. Blood flow to other organs, including the uterus, is reduced. As a result, the fetus is deprived of a full supply of oxygen and nutrients.

Maternal stress hormones also cross the placenta, causing a dramatic rise in fetal stress hormones (evident in the amniotic fluid) and, therefore, in fetal heart rate, blood pressure, blood

glucose, and activity level (Kinsella & Monk, 2009; Weinstock, 2008). Excessive fetal stress may permanently alter fetal neurological functioning, thereby heightening stress reactivity in later life. Recall from Chapter 2 that epigenetic changes (gene methylation) may be partly or largely responsible. Infants and children of mothers who experienced severe prenatal anxiety display cortisol levels that are either abnormally high or abnormally low, both of which signal reduced physiological capacity to manage stress.

Maternal emotional stress during pregnancy is associated with diverse negative behavioral outcomes in children and adolescents, including anxiety, short attention span, anger, aggression, overactivity, and lower intelligence test scores, above and beyond the impact of other risks, such as maternal smoking during pregnancy, low birth weight, postnatal maternal anxiety, and low SES (Coall et al., 2015; Monk, Georgieff, & Osterholm, 2013). Furthermore, similar to prenatal malnutrition, overwhelming the fetus with maternal stress hormones heightens susceptibility to later illness, including cardiovascular disease and diabetes in adulthood (Reynolds, 2013).

But stress-related prenatal complications are greatly reduced when mothers have partners, other family members, and friends who offer social support (Bloom et al., 2013; Luecken et al., 2013). The relationship of social support to positive pregnancy outcomes and subsequent child development is particularly strong for economically disadvantaged women, who often lead highly stressful lives (see the Social Issues: Health box on page 90).

**Rh Factor Incompatibility.** When inherited blood types of mother and fetus differ, serious problems sometimes result. The most common cause of these difficulties is **Rh factor incompatibility**. When the mother is Rh-negative (lacks the Rh blood protein) and the father is Rh-positive (has the protein), the baby may inherit the father’s Rh-positive blood type. If even a little of a fetus’s Rh-positive blood crosses the placenta into the Rh-negative mother’s bloodstream, she begins to form antibodies to the foreign Rh protein. If these enter the fetus’s system, they destroy red blood cells, reducing the oxygen supply to organs and tissues. Intellectual disability, miscarriage, heart damage, and infant death can occur.

It takes time for the mother to produce Rh antibodies, so firstborn children are rarely affected. The danger increases with each additional pregnancy. Fortunately, Rh incompatibility can be prevented in most cases. After the birth of each Rh-positive baby, Rh-negative mothers are routinely given a vaccine to prevent the buildup of antibodies.

**Maternal Age.** In Chapter 2, we noted that women who delay childbearing until their thirties or forties face increased risk of infertility, miscarriage, and babies with chromosomal defects. Are other pregnancy complications more common for older mothers? Research indicates that healthy women in their thirties have about the same rates as those in their twenties. Thereafter,

## Social Issues: Health

### The Nurse–Family Partnership: Reducing Maternal Stress and Enhancing Child Development Through Social Support

**A**t age 17, Denise—an unemployed high-school dropout living with her disapproving parents—gave birth to Tara. Having no one to turn to for help during pregnancy and beyond, Denise felt overwhelmed and anxious much of the time. Tara was premature and cried uncontrollably, slept erratically, and suffered from frequent minor illnesses throughout her first year. When she reached school age, she had trouble keeping up academically, and her teachers described her as distractible, unable to sit still, angry, and uncooperative.

The Nurse–Family Partnership—currently implemented in hundreds of counties across 43 U.S. states, in six tribal communities, in the U.S. Virgin Islands, and internationally in Australia, Canada, the Netherlands, and the United Kingdom—is a voluntary home visiting program for first-time, low-income expectant mothers like Denise. Its goals are to reduce pregnancy and birth complications, promote competent early caregiving, and improve family conditions, thereby protecting children from lasting adjustment difficulties.

A registered nurse visits the home weekly during the first month after enrollment, twice a month during the remainder of pregnancy and through the middle of the child’s second year, and then monthly until age 2. In these sessions, the nurse provides the mother with intensive social support—a sympathetic ear; assistance in accessing health and other community services and the help of family members (especially fathers and grandmothers); and encouragement to finish high school, find work, and engage in future family planning.

To evaluate the program’s effectiveness, researchers randomly assigned large samples of mothers at risk for high prenatal stress (due to teenage pregnancy, poverty, and other negative life conditions) to nurse-visiting or comparison conditions (just prenatal care, or prenatal care plus infant referral for developmental problems). Families were followed

COURTESY OF NURSE–FAMILY PARTNERSHIP

The Nurse–Family Partnership provides this first-time, low-income mother with regular home visits from a registered nurse. In follow-up research, children of home-visited mothers developed more favorably—cognitively, emotionally, and socially—than comparison children.

through their child’s school-age years and, in one experiment, into adolescence (Kitzman et al., 2010; Olds et al., 2004, 2007; Rubin et al., 2011).

As kindergartners, Nurse–Family Partnership children obtained higher language and intelligence test scores. And at both ages 6 and 9, the children of home-visited mothers in the poorest mental health during pregnancy exceeded comparison children in academic achievement and displayed fewer behavior problems. Furthermore, from their baby’s birth on, home-visited mothers were on a more favorable life course: They had fewer subsequent births, longer intervals between their first and second births, more frequent contact with the child’s father, more stable intimate partnerships, less welfare dependence, and a greater sense of control over their lives—key factors in reducing subsequent maternal stress and in protecting children’s development. Perhaps for these reasons, adolescent children of home-visited mothers continued to be advantaged in

academic achievement and reported less alcohol use and drug-taking than comparison-group agemates.

Other findings revealed that professional nurses, compared with trained paraprofessionals, were far more effective in preventing outcomes associated with prenatal stress, including high infant fearfulness to novel stimuli and delayed mental development (Olds et al., 2002). Nurses were probably more proficient in individualizing program guidelines to fit the strengths and challenges faced by each family. They also might have had unique legitimacy as experts in the eyes of stressed mothers, more easily convincing them to take steps to reduce pregnancy complications that can trigger persisting developmental problems—such as those Tara displayed.

The Nurse–Family Partnership is highly cost-effective (Miller, 2015). For \$1 spent, it saves more than five times as much in public spending on pregnancy complications, preterm births, and child and youth health, learning, and behavior problems.

**FIGURE 3.4 Relationship of maternal age to prenatal and birth complications.** Complications increase after age 40, with a sharp rise between 50 and 55 years. See elsewhere on this page for a description of preeclampsia. (Based on Salihu et al., 2003.)

as Figure 3.4 reveals, complication rates increase, with a sharp rise among women age 50 to 55—an age at which, because of menopause (end of menstruation) and aging reproductive organs, few women can conceive naturally (Salihu et al., 2003; Usta & Nassar, 2008).

In the case of teenage mothers, does physical immaturity cause prenatal complications? As we will see in Chapter 11, infants born to teenagers have a higher rate of problems, but not directly because of maternal age. Most pregnant teenagers come from low-income backgrounds, where stress, poor nutrition, and health problems are common. Also, many are afraid to seek medical care. And in the United States, although the Affordable Care Act has greatly increased health insurance for pregnant adolescents, not all have full coverage.

### LOOK and LISTEN

List prenatal environmental factors that can compromise later academic performance and social adjustment. Ask several adults who hope someday to be parents to explain what they know about each factor. How great is their need for prenatal education?

## The Importance of Prenatal Health Care

Yolanda's pregnancy, like most others, was free of complications. But unexpected difficulties can arise, especially if

mothers have health problems. For example, the 5 percent of pregnant women who have diabetes need careful monitoring. Extra glucose in the diabetic mother's bloodstream causes the fetus to grow larger than average, making pregnancy and birth problems more common. Maternal high blood glucose also compromises prenatal brain development: It is linked to poorer memory and learning in infancy and early childhood (Riggins et al., 2009). Another complication, experienced by 5 to 10 percent of pregnant women, is *preeclampsia* (sometimes called *toxemia*), in which blood pressure increases sharply and the face, hands, and feet swell in the last half of pregnancy. If untreated, preeclampsia can cause convulsions in the mother and fetal death. Usually, hospitalization, bed rest, and drugs can lower blood pressure to a safe level (Vest & Cho, 2012). If not, the baby must be delivered at once.

Unfortunately, 6 percent of pregnant women in the United States wait until after the first trimester to seek prenatal care or receive none at all. Inadequate care is far more common among adolescent and low-income, ethnic minority mothers. Their infants are three times as likely to be born underweight and five times as likely to die as are babies of mothers who receive early medical attention (Child Trends, 2015c). Although government-sponsored health services for low-income pregnant women have expanded, some do not qualify and must pay for at least part of their care. As we will see when we take up birth complications, in nations where affordable medical care is universally available, such as Australia, Canada, Japan, and European countries, late-care pregnancies and maternal and infant health problems are greatly reduced.

Besides financial hardship, some mothers have other reasons for not seeking early prenatal care. These include *situational barriers* (difficulty finding a doctor, getting an appointment, and arranging transportation) and *personal barriers* (psychological stress, the demands of taking care of other young children, family crises, and ambivalence about the pregnancy). Many also engage in high-risk behaviors, such as smoking and drug abuse, which they do not want to reveal to health professionals (Kitsantas, Gaffney, & Cheema, 2012). These women, who receive little or no prenatal care, are among those who need it most!

Clearly, public education about the importance of early and sustained prenatal care for all pregnant women is badly needed. For women who are young, less-educated, low-income, or under stress and therefore at risk for inadequate prenatal care, assistance in making appointments, drop-in child-care centers, and free or low-cost transportation are vital.

Culturally sensitive health-care practices are also helpful. In a strategy called *group prenatal care*, after each medical checkup, trained leaders provide ethnic minority expectant mothers with a group discussion session, which is conducted in their native language and encourages them to talk about important health issues. Compared to mothers receiving traditional brief appointments with little opportunity to ask questions, participants engaged in more health-promoting behaviors and gave birth to babies with a reduced incidence of

## Applying what we Know

### Do's and Don'ts for a Healthy Pregnancy

#### DO

Do make sure that you have been vaccinated against infectious diseases that are dangerous to the embryo and fetus, such as rubella, before you get pregnant. Most vaccinations are not safe during pregnancy.

Do see a doctor as soon as you suspect that you are pregnant, and continue to get regular medical checkups throughout pregnancy.

Do eat a well-balanced diet and take vitamin–mineral supplements, as prescribed by your doctor, both prior to and during pregnancy. Gain 25 to 30 pounds gradually.

Do obtain literature from your doctor, library, or bookstore about prenatal development. Ask your doctor about anything that concerns you.

Do keep physically fit through moderate exercise. If possible, join a special exercise class for expectant mothers.

Do avoid emotional stress. If you are a single expectant mother, find a relative or friend on whom you can rely for emotional support.

Do get plenty of rest. An overtired mother is at risk for pregnancy complications.

Do enroll in a prenatal and childbirth education class with your partner or other companion. When parents know what to expect, the nine months before birth can be one of the most joyful times of life.

#### DON'T

Don't take any drugs without consulting your doctor.

Don't smoke. If you have already smoked during part of your pregnancy, cut down or, better yet, quit. If other members of your family smoke, ask them to quit or to smoke outside.

Don't drink alcohol from the time you decide to get pregnant.

Don't engage in activities that might expose your embryo or fetus to environmental hazards, such as radiation or chemical pollutants. If you work in an occupation that involves these agents, ask for a safer assignment or a leave of absence.

Don't engage in activities that might expose your embryo or fetus to harmful infectious diseases, such as toxoplasmosis.

Don't choose pregnancy as a time to go on a diet.

Don't gain too much weight during pregnancy. A very large weight gain is associated with complications.

prematurity and low birth weight (Tandon et al., 2012). Refer to Applying What We Know above, which lists “do’s and don’ts” for a healthy pregnancy, based on our discussion of the prenatal environment.

© MARK PETERSON/REDFUX

Expectant mothers are invited to ask questions during a group prenatal care session. Ethnic minority mothers who receive culturally sensitive prenatal care engage in more health-promoting behaviors and have healthier newborns.

## Ask yourself

**CONNECT** Using what you learned about research strategies in Chapter 1, explain why it is difficult to determine the prenatal effects of many environmental agents, such as drugs and pollution.

**APPLY** Nora, pregnant for the first time, believes that a few cigarettes and a glass of wine a day won't be harmful. Provide Nora with research-based reasons for not smoking or drinking.

**REFLECT** If you had to choose five environmental influences to publicize in a campaign aimed at promoting healthy prenatal development, which ones would you choose, and why?

## Childbirth

**3.5** Describe the three stages of childbirth, the baby's adaptation to labor and delivery, and the newborn baby's appearance.

Although Yolanda and Jay completed my course three months before their baby was born, both agreed to return to share their experiences with my next class. Two-week-old Joshua came along as well. Yolanda and Jay's story revealed that the birth of a baby is one of the most dramatic and emotional events in human

experience. Jay was present throughout Yolanda's labor and delivery. Yolanda explained:

By morning, we knew I was in labor. It was Thursday, so we went in for my usual weekly appointment. The doctor said, yes, the baby was on the way, but it would be a while. He told us to go home and relax and come to the hospital in three or four hours. We checked in at 3 in the afternoon; Joshua arrived at 2 o'clock the next morning. When, finally, I was ready to deliver, it went quickly; a half hour or so and some good hard pushes, and there he was! His face was red and puffy, and his head was misshapen, but I thought, "Our son! I can't believe he's really here."

Jay was also elated by Joshua's birth. "It was awesome, indescribable. I can't stop looking and smiling at him," Jay said, holding Joshua over his shoulder and patting and kissing him gently. In the following sections, we explore the experience of childbirth, from both the parents' and the baby's point of view.

## The Stages of Childbirth

It is not surprising that childbirth is often referred to as labor. It is the hardest physical work a woman may ever do. A complex series of hormonal changes between mother and fetus initiates the process, which naturally divides into three stages (see Figure 3.5):

1. *Dilation and effacement of the cervix.* This is the longest stage of labor, lasting an average of 12 to 14 hours with a first birth and 4 to 6 hours with later births. Contractions of the uterus gradually become more frequent and powerful, causing the cervix, or uterine opening, to widen and thin to nothing, forming a clear channel from the uterus into the birth canal, or vagina.
2. *Delivery of the baby.* This stage is much shorter, lasting about 50 minutes for a first birth and 20 minutes in later births. Strong contractions of the uterus continue, but the

**FIGURE 3.5** The three stages of childbirth.

mother also feels a natural urge to squeeze and push with her abdominal muscles. As she does so with each contraction, she forces the baby down and out.

3. *Delivery of the placenta.* Labor comes to an end with a few final contractions and pushes. These cause the placenta to separate from the wall of the uterus and be delivered in about 5 to 10 minutes.

## The Baby's Adaptation to Labor and Delivery

At first glance, labor and delivery seem like a dangerous ordeal for the baby. The strong contractions exposed Joshua's head to a great deal of pressure, and they squeezed the placenta and the umbilical cord repeatedly. Each time, Joshua's supply of oxygen was temporarily reduced.

Fortunately, healthy babies are equipped to withstand these traumas. The force of the contractions intensifies the baby's production of stress hormones. Unlike during pregnancy, when excessive stress endangers the fetus, during childbirth high levels of infant cortisol and other stress hormones are adaptive. They help the baby withstand oxygen deprivation by sending a rich supply of blood to the brain and heart (Gluckman, Sizonenko, & Bassett, 1999). In addition, stress hormones prepare the baby to breathe by causing the lungs to absorb any remaining fluid and by expanding the bronchial tubes (passages leading to the lungs). Finally, stress hormones arouse the infant into alertness. Joshua was born wide awake, ready to interact with the surrounding world.

## The Newborn Baby's Appearance

Parents are often surprised at the odd-looking newborn—a far cry from the storybook image they may have had in their minds. The average newborn is 20 inches long and 7½ pounds in weight; boys tend to be slightly longer and heavier than girls. The head is

LILLIAN WILSON/RISER/GETTY IMAGES

To accommodate the well-developed brain, a newborn's head is large in relation to the trunk and legs. This newborn's body readily turns pink as she takes her first few breaths.

large in comparison to the trunk and legs, which are short and bowed. This combination of a large head (with its well-developed brain) and a small body means that human infants learn quickly in the first few months of life. But, unlike most other mammals, they cannot get around on their own until much later.

Even though newborn babies may not match parents' idealized image, some features do make them attractive (Luo, Li, & Lee, 2011). Their round faces, chubby cheeks, large foreheads, and big eyes make adults feel like picking them up and cuddling them.

## Assessing the Newborn's Physical Condition: The Apgar Scale

Infants who have difficulty making the transition to life outside the uterus require special help at once. To assess the newborn's physical condition quickly, doctors and nurses use the **Apgar Scale**. As Table 3.3 shows, a rating of 0, 1, or 2 on each of

**TABLE 3.3**  
The Apgar Scale

SIGN <sup>a</sup>	RATING		
	0	1	2
Heart rate	No heartbeat	Under 100 beats per minute	100 to 140 beats per minute
Respiratory effort	No breathing for 60 seconds	Irregular, shallow breathing	Strong breathing and crying
Reflex irritability (sneezing, coughing, and grimacing)	No response	Weak reflexive response	Strong reflexive response
Muscle tone	Completely limp	Weak movements of arms and legs	Strong movements of arms and legs
Color <sup>b</sup>	Blue body, arms, and legs	Body pink with blue arms and legs	Body, arms, and legs completely pink

<sup>a</sup>To remember these signs, you may find it helpful to use a technique in which the original labels are reordered and renamed as follows: color = **A**ppearance; heart rate = **P**ulse; reflex irritability = **G**rimace; muscle tone = **A**ctivity; and respiratory effort = **R**espiration. Together, the first letters of the new labels spell **Apgar**.

<sup>b</sup>The skin tone of nonwhite babies makes it difficult to apply the "pink" color criterion. However, newborns of all races can be rated for pinkish glow resulting from the flow of oxygen through body tissues.

five characteristics is made at 1 minute and again at 5 minutes after birth. A combined Apgar score of 7 or better indicates that the infant is in good physical condition. If the score is between 4 and 6, the baby needs assistance in establishing breathing and other vital signs. If the score is 3 or below, the infant is in serious danger and requires emergency medical attention (Apgar, 1953). Two Apgar ratings are given because some babies have trouble adjusting at first but do quite well after a few minutes.

## Approaches to Childbirth

**3.6** Describe natural childbirth and home delivery, noting benefits and concerns associated with each.

Childbirth practices, like other aspects of family life, are heavily influenced by culture. In many village and tribal societies, expectant mothers are well-acquainted with the childbirth process. For example, the Jarara of South America and the Pukapukan of the Pacific Islands treat birth as a vital part of daily life. The Jarara mother gives birth in full view of the entire community, including small children. The Pukapukan girl is so familiar with the events of labor and delivery that she frequently can be seen playing at it. Using a coconut to represent the baby, she stuffs it inside her dress, imitates the mother's pushing, and lets the nut fall at the proper moment. In most nonindustrialized cultures, women are assisted—though often not by medical personnel—during labor and delivery. Among the Mende of Sierra Leone, birth attendants, who are appointed by the village chief, visit mothers before and after birth to provide advice and practice traditional strategies during labor to quicken delivery, including massaging the abdomen and supporting the woman in a squatting position (Dorwie & Pacquiao, 2014).

In Western nations, childbirth has changed dramatically over the centuries. Before the late 1800s, birth usually took place at home and was a family-centered event. The industrial revolution brought greater crowding to cities, along with new health problems. As a result, childbirth moved from home to hospital, where the health of mothers and babies could be protected. Once doctors assumed responsibility for childbirth, women's knowledge of it declined, and relatives and friends no longer participated (Borst, 1995).

By the 1950s and 1960s, women had begun to question the medical procedures used during labor. Many felt that routine use of strong drugs and delivery instruments had robbed them of a precious experience and was often neither necessary nor safe for the baby. Gradually, a natural childbirth movement arose in Europe and spread to North America. Its purpose was to make hospital birth as comfortable and rewarding for mothers as possible. Today, most hospitals offer birth centers that are family-centered and homelike. *Freestanding birth centers*, which permit greater maternal control over labor and delivery, including choice of delivery positions, presence of family

© MICHAEL G. SEAMANS/PULITZER CENTER ON CRISIS REPORTING

In Sierra Leone, a new mother rests comfortably after giving birth to twins. She had her first twin at home, assisted by village birth attendants. After complications arose, the birth attendants took her to a clinic, where they collaborated with nurses in delivering her second twin. Throughout, cultural practices remained a part of this birth experience.

members and friends, and early contact between parents and baby, also exist. And a small number of North American women reject institutional birth and choose to have their babies at home.

## Natural, or Prepared, Childbirth

Yolanda and Jay chose **natural, or prepared, childbirth**—a group of techniques aimed at reducing pain and medical intervention and making childbirth a rewarding experience. Most natural childbirth programs draw on methods developed by Grantly Dick-Read (1959) in England and Fernand Lamaze (1958) in France. These physicians recognized that cultural attitudes had taught women to fear the birth experience. An anxious, frightened woman in labor tenses her muscles, heightening the pain that usually accompanies strong contractions.

In a typical natural childbirth program, the expectant mother and a companion (a partner, relative, or friend) participate in three activities:

- *Classes.* Yolanda and Jay attended a series of classes in which they learned about the anatomy and physiology of labor and delivery. Knowledge about the birth process reduces a mother's fear.
- *Relaxation and breathing techniques.* During each class, Yolanda was taught relaxation and breathing exercises aimed at counteracting the pain of uterine contractions.
- *Labor coach.* Jay learned how to help Yolanda during childbirth by reminding her to relax and breathe, massaging her back, supporting her body, and offering encouragement and affection.

Social support is important to the success of natural childbirth. In Guatemalan and American hospitals that routinely isolated patients during childbirth, some mothers were randomly assigned a *doula*—a Greek word referring to a trained lay attendant—who stayed with them throughout labor and delivery, talking to them, holding their hands, and rubbing their backs to promote relaxation. These mothers had shorter labors and fewer birth complications than women not given supportive companionship. Guatemalan mothers who received doula support also interacted more positively with their newborns, talking, smiling, and gently stroking (Kennell et al., 1991; Sosa et al., 1980).

Other studies indicate that mothers who are supported during labor and delivery—either by a lay birth attendant or by a relative or friend with doula training—less often have instrument-assisted or cesarean (surgical) deliveries or need medication to control pain. Also, their babies' Apgar scores are higher, and they are more likely to be breastfeeding at a two-month follow-up (Campbell et al., 2006, 2007; Hodnett et al., 2012; McGrath & Kennell, 2008). Social support also makes Western hospital-birth customs more acceptable to women from parts of the world where assistance from family and community members is the norm (Dundek, 2006).

## Home Delivery

Home birth has always been popular in certain industrialized nations, such as England, the Netherlands, and Sweden. The

ANDERSEN ROSS/BRAND X PICTURES/GETTY IMAGES

After a home birth, the midwife and a lay attendant provide support to the new mother. For healthy women attended by a well-trained doctor or midwife, home birth is as safe as hospital birth.

number of American women choosing to have their babies at home rose during the 1970s and 1980s but remains small, at less than 1 percent (Martin et al., 2015). Although some home births are attended by doctors, many more are handled by *certified nurse-midwives*, who have degrees in nursing and additional training in childbirth management.

Is it just as safe to give birth at home as in a hospital? For healthy women without pregnancy complications who are assisted by a well-trained doctor or midwife, it seems so because complications rarely occur (Cheyney et al., 2014). However, if attendants are not carefully trained and prepared to handle emergencies, the likelihood of infant disability and death is high (Grünebaum et al., 2015). When mothers are at risk for any kind of complication, the appropriate place for labor and delivery is the hospital, where life-saving treatment is available.

## Medical Interventions

**3.7** List common medical interventions during childbirth, circumstances that justify their use, and any dangers associated with each.

Four-year-old Melinda walks with a halting, lumbering gait and has difficulty keeping her balance. She has *cerebral palsy*, a general term for a variety of impairments in muscle coordination caused by brain damage before, during, or just after birth. One out of every 500 American children has cerebral palsy. For about 10 percent, including Melinda, the brain damage was caused by **anoxia**, or inadequate oxygen supply, during labor and delivery (Clark, Ghulmiyyah, & Hankins, 2008; McIntyre et al., 2013). Melinda was in **breech position**, turned so that the buttocks or feet would be delivered first, and the umbilical cord was wrapped around her neck. Her mother had gotten pregnant accidentally, was frightened and alone, and arrived at the hospital at the last minute. Had she come to the hospital earlier, doctors could have monitored Melinda's condition and delivered her surgically as soon as squeezing of the umbilical cord led to distress, thereby reducing the damage or preventing it entirely.

In cases like Melinda's, medical interventions are clearly justified. But in others, they can interfere with delivery and even pose new risks. In the following sections, we examine some commonly used medical procedures during childbirth.

## Fetal Monitoring

**Fetal monitors** are electronic instruments that track the baby's heart rate during labor. An abnormal heartbeat pattern may indicate that the baby is in distress due to anoxia and needs to be delivered immediately. Continuous fetal monitoring, which is required in most U.S. hospitals, is used in over 85 percent of U.S. births (Ananth et al., 2013). The most popular type of monitor is strapped across the mother's abdomen throughout labor. A second, more accurate method involves threading a recording

device through the cervix and placing it directly under the baby's scalp.

Fetal monitoring is a safe medical procedure that has saved the lives of many babies in high-risk situations. But in healthy pregnancies, it does not reduce the already low rates of infant brain damage and death. Furthermore, most infants have some heartbeat irregularities during labor, so critics worry that fetal monitors identify many babies as in danger who, in fact, are not. Monitoring is linked to an increase in the number of instrument and cesarean (surgical) deliveries, practices we will discuss shortly (Alfirevic, Devane, & Gyte, 2013). In addition, some women complain that the devices are uncomfortable and interfere with the normal course of labor.

Still, fetal monitors will probably continue to be used routinely in the United States, even though they are not necessary in most cases. Doctors fear that they will be sued for malpractice if an infant dies or is born with problems and they cannot show they did everything possible to protect the baby.

## Labor and Delivery Medication

Some form of medication is used in more than 80 percent of U.S. births (Declercq et al., 2014). *Analgesics*, drugs used to relieve pain, may be given in mild doses during labor to help a mother relax. *Anesthetics* are a stronger type of painkiller that blocks sensation. Currently, the most common approach to controlling pain during labor is *epidural analgesia*, in which a regional pain-relieving drug is delivered continuously through a catheter into a small space in the lower spine. Unlike older spinal block procedures, which numb the entire lower half of the body, epidural analgesia limits pain reduction to the pelvic region. Because the mother retains the capacity to feel the pressure of the contractions and to move her trunk and legs, she is able to push during the second stage of labor.

Although pain-relieving drugs help women cope with childbirth and enable doctors to perform essential medical interventions, they also can cause problems. Epidural analgesia, for example, weakens uterine contractions. As a result, labor is prolonged, and the chances of instrument delivery or cesarean (surgical) birth increase. And because drugs rapidly cross the placenta, exposed newborns are at risk for respiratory distress (Kumar et al., 2014). They also tend to have lower Apgar scores, to be sleepy and withdrawn, to suck poorly during feedings, and to be irritable when awake (Eltzschig, Lieberman, & Camann, 2003; Platt, 2014). Although no confirmed long-term consequences for development exist, the negative impact of these drugs on the newborn's adjustment supports the current trend to limit their use.

## Cesarean Delivery

A **cesarean delivery** is a surgical birth; the doctor makes an incision in the mother's abdomen and lifts the baby out of the uterus. Forty years ago, cesarean delivery was rare. Since then, cesarean rates have climbed internationally, reaching 16 percent in Finland, 24 percent in New Zealand, 26 percent in Canada, 31

percent in Australia, and 33 percent in the United States (Martin et al., 2015; OECD, 2013b).

Cesareans have always been warranted by medical emergencies, such as Rh incompatibility, premature separation of the placenta from the uterus, or serious maternal infection (for example, the herpes simplex 2 virus, which can infect the baby during a vaginal delivery). Cesareans are also justified in breech births, in which the baby risks head injury or anoxia (as in Melinda's case). But the infant's exact position makes a difference: Certain breech babies fare just as well with a normal delivery as with a cesarean (Vistad et al., 2013). Sometimes the doctor can gently turn the baby into a head-down position during the early part of labor.

Until recently, many women who have had a cesarean have been offered the option of a vaginal birth in subsequent pregnancies. But growing evidence indicates that compared with repeated cesareans, a natural labor after a cesarean is associated with slightly increased rates of rupture of the uterus and infant death (Hunter, 2014). As a result, the rule "Once a cesarean, always a cesarean" has made a comeback.

Repeated cesareans, however, do not explain the worldwide rise in cesarean deliveries. Instead, medical control over childbirth is largely responsible. Because many needless cesareans are performed, pregnant women should ask questions about the procedure when choosing a doctor. Although the operation itself is safe, mother and baby require more time for recovery. Anesthetic may have crossed the placenta, making cesarean newborns sleepy and unresponsive and putting them at increased risk for breathing difficulties (Ramachandrappa & Jain, 2008).

## Ask yourself

**CONNECT** How might natural childbirth positively affect the parent–newborn relationship? Explain how your answer illustrates bidirectional influences between parent and child, emphasized in ecological systems theory.

**APPLY** Sharon, a heavy smoker, has just arrived at the hospital in labor. Which medical intervention discussed in the preceding sections is her doctor justified in using? (For help in answering this question, review the prenatal effects of tobacco on page 84.)

**REFLECT** If you were an expectant parent, would you choose home birth? Why or why not?

## Preterm and Low-Birth-Weight Infants

**3.8** Describe risks associated with preterm birth and low birth weight, along with effective interventions.

Babies born three weeks or more before the end of a full 38-week pregnancy or who weigh less than 5½ pounds (2,500 grams) have for many years been referred to as "premature." A wealth of research indicates that premature babies are at risk for many

**FIGURE 3.6 Rates of infant survival and child disabilities by length of pregnancy.** In a follow-up of more than 2,300 babies born between 23 and 28 weeks gestation, the percentage who survived decreased and the percentage who displayed moderate to severe disabilities (assessed during the preschool years) increased with reduced length of pregnancy. Severe disabilities included cerebral palsy (unlikely to ever walk), severely delayed mental development, deafness, and blindness. Moderate disabilities included cerebral palsy (able to walk with assistance), moderately delayed mental development, and hearing impairments partially correctable with a hearing aid. (Adapted from Bolisetty et al., 2006.)

problems. Birth weight is the best available predictor of infant survival and healthy development. Many newborns who weigh less than 3½ pounds (1,500 grams) experience difficulties that are not overcome, an effect that becomes stronger as length of pregnancy and birth weight decrease (see Figure 3.6) (Bolisetty et al., 2006; Wilson-Ching et al., 2013). Brain abnormalities, delayed physical growth, frequent illness, sensory impairments, poor motor coordination, inattention, overactivity, language delays, low intelligence test scores, deficits in school learning, and emotional and behavior problems are some of the difficulties that persist through childhood and adolescence and into adulthood (Hutchinson et al., 2013; Lawn et al., 2014; Lemola, 2015).

About 11 percent of American infants are born early, and 8 percent are born underweight. The two risk factors often co-occur, and they can strike unexpectedly. But the problem is highest among poverty-stricken women (Martin et al., 2015). These mothers, as noted earlier, are more likely to be under stress, undernourished, and exposed to other harmful environmental influences. In addition, they often do not receive adequate prenatal care.

Recall from Chapter 2 that prematurity is also common in multiple births. About 55 percent of twins and more than 90 percent of triplets are born early and low birth weight (Martin et al., 2015). Because space inside the uterus is restricted, multiples gain less weight than singletons in the second half of pregnancy.

## Preterm versus Small-for-Date Infants

Although preterm and low-birth-weight infants face many obstacles to healthy development, most go on to lead normal lives;

about half of those born at 23 to 24 weeks gestation and weighing only a couple of pounds at birth have no disability (refer again to Figure 3.6). To better understand why some babies do better than others, researchers divide them into two groups. **Preterm infants** are born several weeks or more before their due date. Although they are small, their weight may still be appropriate, based on time spent in the uterus. **Small-for-date infants** are below their expected weight considering length of the pregnancy. Some small-for-date infants are actually full-term. Others are preterm infants who are especially underweight.

Small-for-date infants—especially those who are also preterm—usually have more serious problems. During the first year, they are more likely to die, catch infections, and show evidence of brain damage. By middle childhood, they are smaller in stature, have lower intelligence test scores, are less attentive, achieve more poorly in school, and are socially immature (Katz et al., 2013; Sullivan et al., 2008; Wilson-Ching et al., 2013). Small-for-date infants probably experienced inadequate nutrition before birth. Perhaps their mothers did not eat properly, the placenta did not function normally, or the babies themselves had defects that prevented them from growing as they should. Consequently, small-for-date infants are especially likely to suffer from neurological impairments that permanently weaken their capacity to manage stress (Osterholm, Hostinar, & Gunnar, 2012). Severe stress, in turn, heightens their susceptibility to later physical and psychological health problems.

Even among preterm newborns whose weight is appropriate for length of pregnancy, just 7 to 14 more days—from 34 to 35 or 36 weeks—greatly reduces rates of illness, costly medical procedures, and lengthy hospital stays (although they need greater medical intervention than full-term babies) (Ananth, Friedman, & Gyamfi-Bannerman, 2013). And despite being relatively low-risk for disabilities, a substantial number of 34-week preterms are below average in physical growth and mildly to moderately delayed in cognitive development in early and middle childhood (Morse et al., 2009; Stephens & Vohr, 2009). In an investigation of over 120,000 New York City births, babies born even 1 or 2 weeks early showed slightly lower reading and math scores at a third-grade follow-up than children who experienced a full-length prenatal period (Noble et al., 2012). These outcomes persisted even after controlling for other factors linked to achievement, such as birth weight and SES. Yet doctors often induce births several weeks preterm, under the misconception that these babies are developmentally “mature.”

## Consequences for Caregiving

Imagine a scrawny, thin-skinned infant whose body is only a little larger than the size of your hand. You try to play with the baby by stroking and talking softly, but he is sleepy and unresponsive. When you feed him, he sucks poorly. During the short, unpredictable periods he is awake, he is usually irritable.

The appearance and behavior of preterm babies can lead parents to be less sensitive in caring for them. Compared with full-term infants, preterm babies—especially those who are very

ill at birth—are less often held close, touched, and talked to gently. At times, mothers of these infants resort to interfering pokes and verbal commands in an effort to obtain a higher level of response from the baby (Feldman, 2007; Forcada-Guex et al., 2006). This may explain why preterm babies as a group are at risk for child abuse.

Research reveals that distressed, emotionally reactive preterm infants are particularly susceptible to the effects of parenting quality: Among a sample of preterm 9-month-olds, the combination of infant negativity and angry or intrusive parenting yielded the highest rates of behavior problems at 2 years of age. But with warm, sensitive parenting, distressed preterm babies' rates of behavior problems were the lowest (Poehlmann et al., 2011). When they are born to isolated, poverty-stricken mothers who cannot provide good nutrition, health care, and parenting, the likelihood of unfavorable outcomes increases. In contrast, parents with stable life circumstances and social supports usually can overcome the stresses of caring for a preterm infant (Ment et al., 2003). In these cases, even sick preterm babies have a good chance of catching up in development by middle childhood.

These findings suggest that how well preterm infants develop has a great deal to do with the parent–child relationship. Consequently, interventions directed at supporting both sides of this tie are more likely to help these infants recover.

## Interventions for Preterm Infants

A preterm baby is cared for in a special Plexiglas-enclosed bed called an *isolette*. Temperature is carefully controlled because these babies cannot yet regulate their own body temperature effectively. To help protect the baby from infection, air is filtered before it enters the isolette. When a preterm infant is fed through a stomach tube, breathes with the aid of a respirator, and receives medication through an intravenous needle, the isolette can be very isolating indeed! Physical needs that otherwise would lead to close contact and other human stimulation are met mechanically.

**Special Infant Stimulation.** In proper doses, certain kinds of stimulation can help preterm infants develop. In some intensive care nurseries, preterm babies can be seen rocking in suspended hammocks, lying on waterbeds designed to replace the gentle motion they would have received while still in the mother's uterus, or listening to soft music—experiences that promote faster weight gain, more predictable sleep patterns, and greater alertness (Arnon et al., 2006; Marshall-Baker, Lickliter, & Cooper, 1998). In one experiment, extremely preterm newborns, born between the 25th and 32nd prenatal weeks, were exposed either to recordings of their mother's voice and heartbeat for several hours each day or to routine hospital noise. At age 1 month, an ultrasound revealed that auditory areas of the brain had grown substantially larger in the maternal sounds group (see Figure 3.7) (Webb et al., 2015). Listening to womblike, familiar rhythmic maternal sounds, as

**FIGURE 3.7** Listening to mother's voice and heartbeat enhances brain development in extremely preterm newborns. Infants born between the 25th and 32nd prenatal weeks were randomly assigned to hear either recordings of their mother's voice and heartbeat for several hours a day or routine, unpatterned hospital noise. After a month's exposure in the intensive care nursery, ultrasound measures showed that the left and right cerebral auditory areas were substantially thicker in the maternal sounds group than the hospital noise group. In addition to highlighting an effective intervention, the results suggest that exposure to soft, rhythmic maternal sounds during pregnancy enhances early brain development. (Based on Webb et al., 2015.)

opposed to the unpredictable din of hospital equipment, promoted brain development.

In baby animals, touching the skin releases certain brain chemicals that support physical growth—effects believed to occur in humans as well. When preterm infants were massaged several times each day in the hospital, they gained weight faster and, at the end of the first year, were advanced in mental and motor development over preterm babies not given this stimulation (Field, 2001; Field, Hernandez-Reif, & Freedman, 2004).

In developing countries where hospitalization is not always possible, skin-to-skin “kangaroo care” is the most readily available intervention for promoting the recovery of preterm babies. It involves placing the infant in a vertical position between the mother's breasts or next to the father's chest (under the parent's clothing) so the parent's body functions as a human incubator. Because of its many physical and psychological benefits, the technique is often used in Western nations as a supplement to hospital intensive care.

Kangaroo skin-to-skin contact fosters improved oxygenation of the baby's body, temperature regulation, sleep, breastfeeding, alertness, and infant survival (Conde-Agudelo, Belizan, &

© PICTURE PARTNERS/ALAMY

In Western nations, kangaroo care may be used to supplement hospital intensive care. Here, a U.S. mother engages in the technique with her fragile newborn.

Diaz-Rossello, 2011; Kaffashi et al., 2013). In addition, the kangaroo position provides the baby with gentle stimulation of all sensory modalities: hearing (through the parent's voice), smell (through proximity to the parent's body), touch (through skin-to-skin contact), and vision (through the upright position). Mothers and fathers practicing kangaroo care feel more confident about caring for their fragile babies, interact more sensitively and affectionately, and feel more attached to them (Dodd, 2005; Feldman, 2007).

Together, these factors may explain why preterm babies given many hours of kangaroo care in their early weeks, compared to those given little or no such care, are more likely to explore novel toys and score higher in mental and motor development during the first year (Bera et al., 2014; Feldman, 2007). In an investigation that followed children born preterm until age 10, those who had experienced kangaroo care, compared with matched controls, displayed a more adaptive cortisol stress response, better organized sleep, more favorable mother-child interaction, and enhanced cognitive development (Feldman, Rosenthal, & Eidelman, 2014). Because of its diverse benefits, most U.S. hospital nurseries now offer kangaroo care to parents and preterm newborns.

**Training Parents in Infant Caregiving Skills.** Interventions that support parents of preterm infants generally teach them how to recognize and respond to the baby's needs. For parents with adequate economic and personal resources to care for a preterm infant, just a few sessions of coaching are linked to enhanced

parent-infant interaction, reduced infant crying and improved sleep, more rapid language development in the second year, and steady gains in mental test performance that equal those of full-term children by middle childhood (Achenbach, Howell, & Aoki, 1993; Newnham, Milgrom, & Skouteris, 2009).

When preterm infants live in stressed, economically disadvantaged households, long-term, intensive intervention is necessary (Guralnick, 2012). In the Infant Health and Development Program, preterm babies born into poverty received a comprehensive intervention. It combined medical follow-up, weekly home visits in which mothers received training in infant care and everyday problem solving, and cognitively stimulating child care from 1 to 3 years of age. More than four times as many intervention children as no-intervention controls (39 versus 9 percent) were within normal range at age 3 in intelligence, psychological adjustment, and physical growth (Bradley et al., 1994). In addition, mothers in the intervention group were more affectionate and more often encouraged play and cognitive mastery in their children—reasons their 3-year-olds may have been developing so favorably (McCarton, 1998).

At ages 5 and 8, children who had attended the child-care program regularly—for more than 350 days over the three-year period—continued to show better intellectual functioning. In contrast, children who attended only sporadically gained little or even lost ground (Hill, Brooks-Gunn, & Waldfogel, 2003). These findings confirm that babies who are both preterm and economically disadvantaged require *intensive* intervention. And special strategies, such as extra adult-child interaction, may be necessary to achieve lasting changes in children with the lowest birth weights.

Nevertheless, even the best caregiving environments cannot always overcome the enormous biological risks associated with extreme preterm and low birth weight. A better course of action is prevention. The high rate of underweight babies in the United States—one of the worst in the industrialized world—could be greatly reduced by improving the health and social conditions described in the Social Issues: Health box on pages 102–103.

## Ask yourself

**CONNECT** List factors discussed in this chapter that increase the chances that an infant will be born underweight. How many of these factors could be prevented by better health care for expectant mothers?

**APPLY** Cecilia and Anna each gave birth to a 3-pound baby seven weeks preterm. Cecilia is single and on welfare. Anna and her partner are happily married and earn a good income. Plan an intervention appropriate for helping each baby develop.

**REFLECT** Many people object to the use of extraordinary medical measures to save extremely low-birth-weight babies because of their high risk for serious developmental problems. Do you agree or disagree? Explain.

## The Newborn Baby's Capacities

**3.9** Describe the newborn baby's reflexes and states of arousal, noting sleep characteristics and ways to soothe a crying baby.

**3.10** Describe the newborn baby's sensory capacities.

**3.11** Why is neonatal behavioral assessment useful?

Newborn infants have a remarkable set of capacities that are crucial for survival and for evoking adult attention and care. In relating to their physical and social worlds, babies are active from the very start.

### Reflexes

A **reflex** is an inborn, automatic response to a particular form of stimulation. Reflexes are the newborn baby's most obvious organized patterns of behavior. As Jay placed Joshua on a table in my classroom, we saw several. When Jay bumped the side of the table, Joshua reacted by flinging his arms wide and bringing them back toward his body. As Yolanda stroked Joshua's cheek, he turned his head in her direction. Look at Table 3.4 and see if you can name the newborn reflexes that Joshua displayed.

Some reflexes have survival value. The rooting reflex helps a breastfed baby find the mother's nipple. Babies display it only when hungry and touched by another person, not when they touch themselves (Rochat & Hespos, 1997). At birth, babies adjust their sucking pressure to how easily milk flows from the nipple (Craig & Lee, 1999). And if sucking were not automatic, our species would be unlikely to survive for a single generation!

Other reflexes probably aided survival during our evolutionary past. For example, the Moro, or "embracing," reflex is believed to have helped infants cling to their mothers when they were carried about all day. If the baby happened to lose support, the reflex caused the infant to embrace and, along with the palmar grasp reflex (so strong during the first week that it can support the baby's entire weight), regain its hold on the mother's body.

Several reflexes help parents and infants establish gratifying interaction. A baby who successfully finds the nipple, sucks easily during feedings, and grasps when the hand is touched encourages parents to respond lovingly and feel competent as caregivers. Reflexes can also help caregivers comfort the baby because they permit infants to control distress and amount of stimulation. For example, on outings with Joshua, Yolanda brought along a pacifier. If he became fussy, sucking helped quiet him until she could feed, change, or hold him.

**TABLE 3.4**  
Some Newborn Reflexes

REFLEX	STIMULATION	RESPONSE	AGE OF DISAPPEARANCE	FUNCTION
Eye blink	Shine bright light at eyes or clap hand near head.	Infant quickly closes eyelids.	Permanent	Protects infant from strong stimulation
Rooting	Stroke cheek near corner of mouth.	Head turns toward source of stimulation.	3 weeks (becomes voluntary turning at this time)	Helps infant find the nipple
Sucking	Place finger in infant's mouth.	Infant sucks finger rhythmically.	Replaced by voluntary sucking after 4 months	Permits feeding
Moro	Hold infant horizontally on back and let head drop slightly, or produce a sudden loud sound against surface supporting infant.	Infant makes an "embracing" motion by arching back, extending legs, throwing arms outward, and then bringing arms in toward the body.	6 months	In human evolutionary past, may have helped infant cling to mother
Palmar grasp	Place finger in infant's hand and press against palm.	Infant spontaneously grasps finger.	3–4 months	Prepares infant for voluntary grasping
Tonic neck	Turn baby's head to one side while infant is lying awake on back.	Infant lies in a "fencing position." One arm is extended in front of eyes on side to which head is turned, other arm is flexed.	4 months	May prepare infant for voluntary reaching
Stepping	Hold infant under arms and permit bare feet to touch a flat surface.	Infant lifts one foot after another in stepping response.	2 months in infants who gain weight quickly; sustained in lighter infants	Prepares infant for voluntary walking
Babinski	Stroke sole of foot from toe toward heel.	Toes fan out and curl as foot twists in.	8–12 months	Unknown

## Social Issues: Health

### A Cross-National Perspective on Health Care and Other Policies for Parents and Newborn Babies

**Infant mortality**—the number of deaths in the first year of life per 1,000 live births—is an index used around the world to assess the overall health of a nation's children. Although the United States has the most up-to-date health-care technology in the world, it has made less progress in reducing infant deaths than many other countries. Over the past three decades, it has slipped in the international rankings, from seventh in the 1950s to thirty-ninth in 2015. Members of America's poor ethnic minorities are at greatest risk, with African-American infants more than twice as likely as white infants to die in the first year of life (U.S. Census Bureau, 2015c, 2015d).

*Neonatal mortality*, the rate of death within the first month of life, accounts for 67 percent of the infant death rate in the United States. Two factors are largely responsible for neonatal mortality. The first is serious physical defects, most of which cannot be prevented. The percentage of babies born with physical defects is about the same in all ethnic and income groups. The second leading cause of neonatal mortality is low birth weight, which is largely preventable.

Widespread poverty and inadequate health-care programs for mothers and young children are largely responsible for these trends. In addition to providing government-

sponsored health-care benefits to all citizens, each country in Figure 3.8 that outranks the United States in infant survival takes extra steps to make sure that pregnant mothers and babies have access to good nutrition, high-quality medical care, and social and economic supports that promote effective parenting.

For example, all Western European nations guarantee women a certain number of prenatal visits at very low or no cost. After a baby is born, a health professional routinely visits the home to provide counseling about infant care and to arrange continuing medical services. Home assistance is especially extensive in the Netherlands (Lamkaddem

**FIGURE 3.8 Infant mortality in 39 nations.** Despite its advanced health-care technology, the United States ranks poorly. It is thirty-ninth in the world, with a death rate of 5.9 infants per 1,000 births. (Based on U.S. Census Bureau, 2015c.)

A few reflexes form the basis for complex motor skills that will develop later. For example, the tonic neck reflex may prepare the baby for voluntary reaching. When infants lie on their backs in this “fencing position,” they naturally gaze at the hand in front of their eyes. The reflex may encourage them to combine vision with arm movements and, eventually, reach for objects.

Certain reflexes—such as the palmar grasp and stepping—drop out early, but the motor functions involved are renewed later. The stepping reflex, for example, looks like a primitive walking response. In infants who gain weight quickly in the weeks after birth, the stepping reflex drops out because thigh and calf muscles are not strong enough to lift the baby’s chubby legs.

et al., 2014). For a token fee, each mother is granted a specially trained maternity helper, who assists with infant care, shopping, house-keeping, meal preparation, and the care of other children for 8 to 10 days after delivery.

Paid, job-protected employment leave is another vital societal intervention for new parents. Sweden has the most generous parental leave program in the world. Mothers can begin maternity leave 60 days prior to expected delivery, extending it to 6 weeks after birth; fathers are granted 2 weeks of birth leave. In addition, either parent can take full leave for 15 months at 80 percent of prior earnings, followed by an additional 3 months at a modest flat rate. Each parent is also entitled to another 18 months of unpaid leave. Even economically less well-off nations provide parental leave benefits. In Bulgaria, new mothers are granted 11 months paid leave, and fathers receive 3 weeks. Furthermore, many countries supplement basic paid leave. In Germany, for example, after a fully paid 3-month leave, a parent may take one more year at a flat rate and additional leave at no pay until the child reaches age 3 (Addati, Cassirer, & Gilchrist, 2014).

Yet in the United States, the federal government mandates *only 12 weeks of unpaid leave* for employees in companies with at least 50 workers. Most women, however, work in smaller businesses, and many of those who work in large enough companies cannot afford to take unpaid leave. And because of financial pressures, many new mothers who are eligible for unpaid work leave take far less than 12 weeks. Similarly, though paternal leave predicts fathers' increased involvement in infant care at the end of the first year, many fathers take little or none at all (Nepomnyaschy & Waldfogel, 2007). In 2002, California became the first state to guarantee a mother or father

paid leave—up to six weeks at half salary, regardless of the size of the company. Since then, the District of Columbia, Hawaii, New Jersey, New York, Rhode Island, Washington, and the territory of Puerto Rico have passed similar legislation.

Nevertheless, 6 weeks of childbirth leave (the norm in the United States) is not enough. Leaves of 6 to 8 weeks or less are linked to increased maternal anxiety, depression, sense of role overload (conflict between work and family responsibilities), and negative interactions with the baby. A leave of 12 weeks or more predicts favorable maternal physical and mental health, supportive marital interaction, and sensitive caregiving (Chatterji & Markowitz, 2012; Feldman, Sussman, & Zigler, 2004). Single women and their babies are most hurt

by the absence of a generous national paid-leave policy. These mothers, who are usually the sole source of support for their families, can least afford to take time from their jobs.

In countries with low infant mortality rates, expectant parents need not wonder how or where they will get health care and other resources to support their baby's development. The powerful impact of universal, high-quality health care, generous parental leave, and other social services on maternal and infant well-being provides strong justification for these policies. Responding to these findings, the Affordable Care Act provides generous grants to U.S. states to cover the cost of evidence-based home-visiting programs that provide comprehensive services to mothers, infants, and young children in high-risk families.

© KAREN PULFER FOCHT/THE COMMERCIAL APPEAL/LANDOV

This doctor works with high-risk pregnancies, delivering babies whose poverty-stricken mothers have had little or no prenatal care. Nations with low poverty rates and government-supported, high-quality health care for pregnant mothers and babies outrank the United States in infant survival.

But if the lower part of the infant's body is dipped in water, the reflex reappears because the buoyancy of the water lightens the load on the baby's muscles (Thelen, Fisher, & Ridley-Johnson, 1984). When stepping is exercised regularly, babies make more reflexive stepping movements and are likely to walk several weeks earlier than if stepping is not practiced (Zelazo et al.,

1993). However, there is no special need for infants to practice the stepping reflex because all normal babies walk in due time.

Refer to Table 3.4 again, and you will see that most newborn reflexes disappear during the first six months, due to a gradual increase in voluntary control over behavior as the cerebral cortex develops. Pediatricians test reflexes carefully because reflexes can

© LAURA DWIGHT PHOTOGRAPHY

In the Moro reflex, loss of support or a sudden loud sound causes the baby to arch his back, extend his legs, throw his arms outward, and then return them toward the body in an “embracing” motion.

reveal the health of the baby’s nervous system. Weak or absent reflexes, overly rigid or exaggerated reflexes, and reflexes that persist beyond the point in development when they should normally disappear can signal brain damage (Schott & Rossor, 2003).

## States of Arousal

Throughout the day and night, newborn infants move in and out of five **states of arousal**, or degrees of sleep and wakefulness, described in Table 3.5. During the first month, these states alternate frequently. The most fleeting is quiet alertness, which usually moves quickly toward fussing and crying. Much to the relief of their fatigued parents, newborns spend the greatest amount of time asleep—about 16 to 18 hours a day. Because the fetus tends to synchronize periods of rest and activity with those of the mother, newborns sleep more at night than during the day (Heraghty et al., 2008). Nevertheless, young babies’ sleep–wake cycles are affected more by fullness–hunger than by darkness–light (Davis, Parker, & Montgomery, 2004).

However, striking individual differences in daily rhythms exist that affect parents’ attitudes toward and interactions with the baby. A few newborns sleep for long periods, increasing the energy their well-rested parents have for sensitive, responsive care. Other babies cry a great deal, and their parents must exert great effort to soothe them. If these parents do not succeed, they may feel less competent and less positive toward their infant.

Furthermore, from birth on, arousal patterns have implications for cognitive development. Babies who spend more time alert probably receive more social stimulation and opportunities to explore and, therefore, may have a slight advantage in mental development. And as with adults, sleep enhances babies’ learning and memory. In one study, eye-blink responses and brain-wave recordings revealed that sleeping newborns readily learned that a tone would be followed by a puff of air to the eye (Fifer et al., 2010). Because young infants spend so much time sleeping, the capacity to learn about external stimuli during sleep may be essential for babies’ adaptation to their surroundings.

© LAURA DWIGHT PHOTOGRAPHY

The palmar grasp reflex is so strong during the first week after birth that many infants can use it to support their entire weight.

© LAURA DWIGHT PHOTOGRAPHY

When held upright under the arms, newborn babies show reflexive stepping movements.

Of the states listed in Table 3.5, the two extremes—sleep and crying—have been of greatest interest to researchers. Each tells us something about normal and abnormal early development.

**Sleep.** Observing Joshua as he slept, Yolanda and Jay wondered why his eyelids and body twitched and his rate of breathing varied. Sleep is made up of at least two states. During irregular, or **rapid-eye-movement (REM), sleep**, brain-wave activity is remarkably similar to that of the waking state. The eyes dart beneath the lids; heart rate, blood pressure, and breathing are uneven; and slight body movements occur. In contrast, during regular, or **non-rapid-eye-movement (NREM), sleep**, the body is almost motionless, and heart rate, breathing, and brain-wave activity are slow and even.

Like children and adults, newborns alternate between REM and NREM sleep. However, they spend far more time in the REM state than they ever will again. REM sleep accounts for 50 percent of a newborn baby’s sleep time. By 3 to 5 years, it has declined to an adultlike level of 20 percent (Louis et al., 1997).

Why do young infants spend so much time in REM sleep? In older children and adults, the REM state is associated with dreaming. Babies probably do not dream, at least not in the same way we do. But researchers believe that the stimulation of REM sleep is vital for growth of the central nervous system (Tarullo, Balsam, & Fifer, 2011). Young infants seem to have a special need for this stimulation because they spend little time in an alert state, when they can get input from the environment. In support of this idea, the percentage of REM sleep is especially great in the fetus and in preterm babies, who are even less able than full-term newborns to take advantage of external stimulation (Peirano, Algarin, & Uauy, 2003).

**TABLE 3.5**  
**Infant States of Arousal**

STATE	DESCRIPTION	DAILY DURATION IN NEWBORN
Regular, or NREM, sleep	The infant is at full rest and shows little or no body activity. The eyelids are closed, no eye movements occur, the face is relaxed, and breathing is slow and regular.	8–9 hours
Irregular, or REM, sleep	Gentle limb movements, occasional stirring, and facial grimacing occur. Although the eyelids are closed, occasional rapid eye movements can be seen beneath them. Breathing is irregular.	8–9 hours
Drowsiness	The infant is either falling asleep or waking up. Body is less active than in irregular sleep but more active than in regular sleep. The eyes open and close; when open, they have a glazed look. Breathing is even but somewhat faster than in regular sleep.	Varies
Quiet alertness	The infant's body is relatively inactive, with eyes open and attentive. Breathing is even.	2–3 hours
Waking activity and crying	The infant shows frequent bursts of uncoordinated body activity. Breathing is very irregular. Face may be relaxed or tense and wrinkled. Crying may occur.	1–4 hours

Source: Wolff, 1966.

Because newborns' normal sleep behavior is organized and patterned, observations of sleep states can help identify central nervous system abnormalities. In infants who are brain-damaged or who have experienced birth trauma, disturbed REM–NREM sleep cycles are often present. Babies with poor sleep organization are likely to be behaviorally disorganized and, therefore, to have difficulty learning and evoking caregiver interactions that enhance their development. In follow-ups during the preschool years, they show delayed motor, cognitive, and language development (Feldman, 2006; Holditch-Davis, Belyea, & Edwards, 2005; Weisman et al., 2011). And the brain-functioning problems that underlie newborn sleep irregularities may culminate in sudden infant death syndrome, a major cause of infant mortality (see the Biology and Environment box on page 106).

**Crying.** Crying is the first way that babies communicate, letting parents know they need food, comfort, or stimulation. During the weeks after birth, all infants have some fussy periods when they are difficult to console. But most of the time, the nature of the cry, combined with the experiences that led up to it, helps guide parents toward its cause. The baby's cry is a complex stimulus that varies in intensity, from a whimper to a message of all-out distress (Wood, 2009). As early as the first few weeks, infants can be identified by the unique vocal "signature" of their cries, which helps parents locate their baby from a distance (Gustafson, Green, & Cleland, 1994).

Young infants usually cry because of physical needs. Hunger is the most common cause, but babies may also cry in response to temperature change when undressed, a sudden noise, or a painful stimulus. Newborns (as well as older babies up to age 6 months) often cry at the sound of another crying baby (Dondi, Simion, & Caltran, 1999; Geangu et al., 2010). Some researchers believe that this response reflects an inborn capacity to react to the suffering of others. Furthermore, crying typically increases during the early weeks, peaks at about 6 weeks, and then declines (Barr, 2001). Because this trend appears in many cultures with vastly different infant care prac-

tices, researchers believe that normal readjustments of the central nervous system underlie it.

The next time you hear an infant cry, notice your own reaction. The sound stimulates a sharp rise in blood cortisol, alertness, and feelings of discomfort in men and women, parents and nonparents alike (de Cock et al., 2015; Yong & Ruffman, 2014). This powerful response is probably innately programmed to ensure that babies receive the care and protection they need to survive.

**Soothing Crying Infants.** Although parents do not always interpret their baby's cry correctly, their accuracy improves with

To soothe his crying infant, this father rocks her gently while talking softly.

## Biology and Environment

### The Mysterious Tragedy of Sudden Infant Death Syndrome

Millie awoke with a start one morning and looked at the clock. It was 7:30, and Sasha had missed both her night waking and her early morning feeding. Wondering if she was all right, Millie and her husband, Stuart, tiptoed into the room. Sasha lay still, curled up under her blanket. She had died silently during her sleep.

Sasha was a victim of **sudden infant death syndrome (SIDS)**, the unexpected death, usually during the night, of an infant younger than 1 year of age that remains unexplained after thorough investigation. In industrialized nations, SIDS is the leading cause of infant mortality between 1 and 12 months, accounting for about 20 percent of these deaths in the United States (Centers for Disease Control and Prevention, 2015i).

SIDS victims usually show physical problems from the beginning. Early medical records of SIDS babies reveal higher rates of prematurity and low birth weight, poor Apgar scores, and limp muscle tone. Abnormal heart rate and respiration and disturbances in sleep–wake activity and in REM–NREM cycles while asleep are also involved (Cornwell & Feigenbaum, 2006; Garcia, Koschnitzky, & Ramirez, 2013). At the time of death, many SIDS babies have a mild respiratory infection (Blood-Siegfried, 2009). This seems to increase the chances of respiratory failure in an already vulnerable baby.

Mounting evidence suggests that impaired brain functioning is a major contributor to SIDS. Between 2 and 4 months, when SIDS is most likely to occur, reflexes decline and are replaced by voluntary, learned responses. Neurological weaknesses may prevent SIDS babies from acquiring behaviors that replace defensive reflexes (Rubens & Sarnat, 2013). As a result, when breathing difficulties occur during sleep, these infants do not wake up, shift their position, or cry out for help. Instead, they simply give in to oxygen deprivation and death. In support of this interpretation, autopsies reveal that the brains of SIDS babies

contain unusually low levels of serotonin (a brain chemical that assists with arousal when survival is threatened) as well as other abnormalities in centers that control breathing and arousal (Salomonis, 2014).

Several environmental factors are linked to SIDS. Maternal cigarette smoking, both during and after pregnancy, as well as smoking by other caregivers, doubles risk of the disorder. Babies exposed to cigarette smoke arouse less easily from sleep and have more respiratory infections (Blackwell et al., 2015). Prenatal abuse of drugs that depress central nervous system functioning (alcohol, opiates, and barbiturates) increases the risk of SIDS as much as fifteenfold (Hunt & Hauck, 2006). Babies of drug-abusing mothers are especially likely to display SIDS-related brain abnormalities (Kinney, 2009).

Infant sleep practices may also be involved. Infants who sleep on their stomachs rather than their backs and who are wrapped very warmly in clothing and blankets less often wake when their breathing is disturbed, especially if they suffer from biological vulnerabilities (Richardson, Walker, & Horne, 2008). In other cases, healthy babies sleeping face down on soft bedding may die from continually breathing their own exhaled breath—deaths due to accidental suffocation and therefore incorrectly classified as SIDS.

SIDS rates are especially high among poverty-stricken minorities (U.S. Department of Health and Human Services, 2015b). In these families, parental stress, substance abuse, reduced access to health care, and lack of knowledge about safe sleep practices are widespread.

Public education efforts are vital for reducing the prevalence of SIDS. The U.S. government's Safe to Sleep campaign encourages parents to create safe sleep environments

BANASTOCK/GETTY IMAGES PLUS/GETTY IMAGES

Public education campaigns encouraging parents to put their infants on their backs to sleep have helped reduce the incidence of SIDS by more than half in many Western nations.

and engage in other protective practices, which are also endorsed by the American Academy of Pediatrics (Barsman et al., 2015). Recommendations include quitting smoking and drug taking, placing infants on their backs, using light sleep clothing, providing a firm sleep surface, and eliminating soft bedding. An estimated 20 percent of SIDS cases would be prevented if all infants had smoke-free homes. Dissemination of information to parents about putting infants down on their backs has cut the incidence of SIDS by more than half in many Western nations (Behm et al., 2012). Another protective measure is pacifier use: Sleeping babies who suck arouse more easily in response to breathing and heart-rate irregularities (Li et al., 2006).

When SIDS does occur, surviving family members require a great deal of help to overcome a sudden and unexpected death. As Millie commented six months after Sasha's death, "It's the worst crisis we've ever been through. What's helped us most are the comforting words of others who've experienced the same tragedy."

## Applying what we Know

### Soothing a Crying Baby

METHOD	EXPLANATION
Talk softly or play rhythmic sounds.	Continuous, monotonous, rhythmic sounds (such as a clock ticking, a fan whirring, or peaceful music) are more effective than intermittent sounds.
Offer a pacifier.	Sucking helps babies control their own level of arousal.
Massage the baby's body.	Stroking the baby's torso and limbs with continuous, gentle motions relaxes the baby's muscles.
Swaddle the baby.	Restricting movement and increasing warmth often soothe a young infant.
Lift the baby to the shoulder and rock or walk.	This combination of physical contact, upright posture, and motion is an effective soothing technique, causing young infants to become quietly alert.
Take the baby for a short car ride or a walk in a baby carriage; swing the baby in a cradle.	Gentle, rhythmic motion of any kind helps lull the baby to sleep.
Combine several of the methods just listed.	Stimulating several of the baby's senses at once is often more effective than stimulating only one.
If these methods do not work, let the baby cry for a short period.	Occasionally, a baby responds well to just being put down and will, after a few minutes, fall asleep.

Sources: Dayton et al., 2015; Evanoo, 2007; St James-Roberts, 2012.

experience. At the same time, they vary widely in responsiveness. Parents who are high in empathy (ability to take the perspective of others in distress) and who hold “child-centered” attitudes toward infant care (for example, believe that babies cannot be spoiled by being picked up) are more likely to respond quickly and sensitively (Cohen-Bendahan, van Doornen, & de Weerth, 2014; Leerkes, 2010).

Fortunately, there are many ways to soothe a crying baby when feeding and diaper changing do not work (see Applying What We Know above). The technique that Western parents usually try first, lifting the baby to the shoulder and rocking or walking, is highly effective. Another common soothing method is swaddling—wrapping the baby snugly in a blanket. The Quechua, who live in the cold, high-altitude desert regions of Peru, dress young babies in layers of clothing and blankets that cover the head and body, a practice that reduces crying and promotes sleep (Tronick, Thomas, & Daltabuit, 1994). It also allows the baby to conserve energy for early growth in the harsh Peruvian highlands.

#### LOOK and LISTEN

In a public setting, watch several parents soothe their crying infants. What techniques did the parents use, and how successful were they?

In many tribal and village societies and non-Western developed nations (such as Japan), babies are in physical contact with their caregivers almost continuously. Infants in these cultures

© DAVID POOLE/ROBERT HARDING

The Bedouin people of the Middle East tightly swaddle young infants, a practice that reduces crying and promotes sleep.

show shorter bouts of crying than their American counterparts (Barr, 2001). When Western parents choose to practice “proximal care” by holding their babies extensively, the amount of crying in the early months is reduced by about one-third (St James-Roberts, 2012).

Fortunately, with age, crying declines. Virtually all researchers agree that parents can lessen older babies’ need to cry by encouraging more mature ways of expressing their desires, such as gestures and vocalizations.

**Abnormal Crying.** Like reflexes and sleep patterns, the infant’s cry offers a clue to central nervous system distress. The cries of brain-damaged babies and those who have experienced prenatal and birth complications are often shrill, piercing, and shorter in duration than those of healthy infants (Green, Irwin, & Gustafson, 2000). Even newborns with a fairly common problem—*colic*, or persistent crying—tend to have high-pitched, harsh-sounding cries (Zeskind & Barr, 1997). Although the cause of colic is unknown, certain newborns, who react especially strongly to unpleasant stimuli, are susceptible. Because their crying is intense, they find it harder to calm down than other babies (St James-Roberts, 2007). Colic generally subsides between 3 and 6 months.

Most parents try to respond to a crying baby with extra care and attention, but sometimes the cry is so unpleasant and the infant so difficult to soothe that parents become frustrated, resentful, and angry. Preterm and ill babies are more likely to be abused by highly stressed parents, who sometimes mention a high-pitched, grating cry as one factor that caused them to lose control and harm the baby (Barr et al., 2014; St James-Roberts, 2012). We will discuss a host of additional influences on child abuse in Chapter 8.

## Sensory Capacities

On his visit to my class, Joshua looked wide-eyed at my bright pink blouse and turned to the sound of his mother’s voice. During feedings, he lets Yolanda know through his sucking rhythm that he prefers the taste of breast milk to a bottle of plain water. Clearly, Joshua has some well-developed sensory capacities. In the following sections, we explore the newborn’s responsiveness to touch, taste, smell, sound, and visual stimulation.

**Touch.** In our discussion of preterm infants, we saw that touch helps stimulate early physical growth. As we will see in Chapter 6, it is vital for emotional development as well. Therefore, it is not surprising that sensitivity to touch emerges early prenatally and is well-developed at birth, as the reflexes listed in Table 3.4 on page 101 reveal. Newborns even use touch to investigate their world. When small objects are placed in their palms, they can distinguish shape (prism versus cylinder) and texture (smooth versus rough), as indicated by their tendency to hold on longer to an object with an unfamiliar shape or texture than to a familiar object (Lejeune et al., 2012; Sann & Streri, 2007).

At birth, infants are highly sensitive to pain. If male newborns are circumcised, anesthetic is sometimes not used because of the risk of giving drugs to a very young infant. Babies often respond with a high-pitched, stressful cry and a dramatic rise in heart rate, blood pressure, palm sweating, pupil dilation, and muscle tension (Lehr et al., 2007; Warnock & Sandrin, 2004). Brain-imaging research suggests that because of central nervous system immaturity, preterm babies, particularly males, feel the pain of a medical injection especially intensely (Bartocci et al., 2006).

Certain local anesthetics for newborns ease the pain of these procedures. As a supplement to pain-relieving medication, offering a nipple that delivers a sugar solution is also helpful; it quickly reduces crying and discomfort in young babies, preterm and full-term alike (Roman-Rodriguez et al., 2014). Breast milk may be especially effective: Even the smell of the milk of the baby’s mother reduces infant distress to a routine blood-test heel stick more effectively than the odor of another mother’s milk or of formula (Badiee, Asghari, & Mohammadzadeh, 2013; Nishitani et al., 2009). And combining sweet liquid with gentle holding by the parent lessens pain even more. Research on infant mammals indicates that physical touch releases *endorphins*—painkilling chemicals in the brain (Gormally et al., 2001).

Allowing a baby to endure severe pain overwhelms the nervous system with stress hormones (Walker, 2013). The result is heightened pain sensitivity, sleep disturbances, feeding problems, and difficulty calming down when upset.

**Taste and Smell.** Facial expressions reveal that newborns can distinguish several basic tastes. Like adults, they relax their facial muscles in response to sweetness, purse their lips when the taste is sour, and show an archlike mouth opening when it is bitter. Similarly, certain odor preferences are present at birth. For example, the smell of bananas or chocolate causes a pleasant facial expression, whereas the odor of rotten eggs makes the infant frown (Steiner, 1979; Steiner et al., 2001). These reactions are important for survival: The food that best supports the infant’s early growth is the sweet-tasting milk of the mother’s breast. Not until 4 months do babies prefer a salty taste to plain water, a change that may prepare them to accept solid foods (Mennella & Beauchamp, 1998).

During pregnancy, the amniotic fluid is rich in tastes and smells that vary with the mother’s diet—early experiences that influence newborns’ preferences. In a study carried out in the Alsatian region of France, where anise is frequently used to flavor foods, researchers tested newborns for their reaction to the anise odor (Schaal, Marlier, & Soussignan, 2000). The mothers of some babies had regularly consumed anise during the last two weeks of pregnancy; the other mothers had never consumed it. When presented with the anise odor on the day of birth, the babies of non-anise-consuming mothers were far more likely to turn away with a negative facial expression (see Figure 3.9). These different reactions were still apparent four days later, even though all mothers had refrained from consuming anise during this time.

**FIGURE 3.9** Examples of facial expressions of newborns exposed to the odor of anise whose mothers' diets differed in anise-flavored foods during late pregnancy. (a) Babies of anise-consuming mothers spent more time turning toward the odor and sucking, licking, and chewing. (b) Babies of non-anise-consuming mothers more often turned away with a negative facial expression. (From B. Schaal, L. Marlier, & R. Soussignan, 2000, "Human Foetuses Learn Odours from Their Pregnant Mother's Diet," *Chemical Senses*, 25, p. 731. © 2000 Oxford University Press, Inc.; permission conveyed through Copyright Clearance Center, Inc.)

Young infants will readily learn to prefer a taste that at first evoked either a negative or a neutral response. Bottle-fed newborns allergic to cow's milk who are given a soy or other vegetable-based substitute (typically very sour and bitter-tasting) soon prefer it to regular formula. When first given solid foods several months later, these infants display an unusual liking for bitter-tasting cereals (Beauchamp & Mennella, 2011). This taste preference is still evident at ages 4 to 5 years, in more positive responses to foods with sour and bitter tastes than shown by age-mates without early vegetable-based formula exposure.

In mammals, including humans, the sense of smell—in addition to playing an important role in feeding—helps mothers and babies identify each other. At 2 to 4 days of age, breastfed babies prefer the odors of their own mother's breast and underarm to those of an unfamiliar lactating mother (Cernoch & Porter, 1985; Marin, Rapisardi, & Tani, 2015). And both breast- and bottle-fed 3- to 4-day-olds orient more and display more mouthing to the smell of unfamiliar human milk than to formula milk, indicating that (even without postnatal exposure) the odor of human milk is more attractive to newborns (Marlier & Schaal, 2005). Newborns' dual attraction to the odors of their mother and of breast milk helps them locate an appropriate food source and, in the process, begin to distinguish their caregiver from other people.

**Hearing.** Newborn infants can hear a wide variety of sounds—sensitivity that improves greatly over the first few months (Johnson & Hannon, 2015). At birth, infants prefer complex sounds, such as noises and voices, to pure tones. And babies only a few days old can tell the difference between a variety of sound patterns: a series of tones arranged in ascending versus descending order; tone sequences with a rhythmic downbeat (as in music) versus those without; utterances with two versus three syllables; the stress patterns of words (“*ma-ma*” versus “*ma-ma*”); happy-sounding speech as opposed to speech with negative or neutral emotional qualities; and even two languages spoken by the same bilingual speaker, as long as those languages differ in their rhythmic features—for example, French versus Russian (Mastropieri & Turkewitz, 1999; Ramus, 2002; Sansavini, Bertocini, & Giovanelli, 1997; Trehub, 2001; Winkler et al., 2009).

Young infants listen longer to human speech than structurally similar nonspeech sounds (Vouloumanos, 2010). And they can detect the sounds of any human language. Newborns make fine-grained distinctions among many speech sounds. For example, when given a nipple that turns on a recording of the “*ba*” sound, babies suck vigorously and then slow down as the novelty wears off. When the sound switches to “*ga*,” sucking picks up, indicating that infants detect this subtle difference. Using this method, researchers have found only a few speech sounds that newborns cannot discriminate. Their ability to perceive sounds not found in their own language is more precise than an adult's (Aldridge, Stillman, & Bower, 2001; Jusczyk & Luce, 2002). These capacities reveal that the baby is marvelously prepared for the awesome task of acquiring language.

Listen carefully to yourself the next time you talk to a young baby. You will probably speak in ways that highlight important parts of the speech stream—use a slow, high-pitched, expressive voice with a rising tone at the ends of phrases and sentences and a pause before continuing. Adults probably communicate this way with infants because they notice that babies are more attentive when they do so. Indeed, newborns prefer speech with these characteristics (Saffran, Werker, & Werner, 2006). They will also suck more on a nipple to hear a recording of their mother's voice than that of an unfamiliar woman and to hear their native language as opposed to a foreign language (Moon, Cooper, & Fifer, 1993; Spence & DeCasper, 1987). These preferences result from hearing the muffled sounds of the mother's voice before birth.

**Vision.** Vision is the least-developed of the newborn baby's senses. Visual structures in both the eye and the brain are not yet fully formed. For example, cells in the *retina*, the membrane lining the inside of the eye that captures light and transforms it into messages that are sent to the brain, are not as mature or densely packed as they will be in several months. The optic nerve that relays these messages, and visual centers in the brain that receive them, will not be adultlike for several years. And muscles of the *lens*, which permit us to adjust our visual focus to varying distances, are weak (Johnson & Hannon, 2015).

As a result, newborns cannot focus their eyes well, and their **visual acuity**, or fineness of discrimination, is limited. At birth,

infants perceive objects at a distance of 20 feet about as clearly as adults do at 600 feet (Slater et al., 2010). In addition, unlike adults (who see nearby objects most clearly), newborn babies see unclearly across a wide range of distances (Banks, 1980; Hainline, 1998). As a result, images such as the parent's face, even from close up, look quite blurred.

Although they cannot yet see well, newborns actively explore their environment by scanning it for interesting sights and tracking moving objects. However, their eye movements are slow and inaccurate (von Hofsten & Rosander, 1998). Joshua's captivation with my pink blouse reveals that he is attracted to bright objects. But despite their preference for colored over gray stimuli, newborn babies are not yet good at discriminating colors. It will take about four months for color vision to become adultlike (Johnson & Hannon, 2015).

## Neonatal Behavioral Assessment

A variety of instruments permit doctors, nurses, and researchers to assess the behavior of newborn babies. The most widely used, T. Berry Brazelton's **Neonatal Behavioral Assessment Scale (NBAS)**, evaluates the newborn's reflexes, muscle tone, state changes, responsiveness to physical and social stimuli, and other reactions (Brazelton & Nugent, 2011). An instrument consisting of similar items, the *Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNS)*, is specially designed for use with newborns at risk for developmental problems because of low birth weight, preterm delivery, prenatal substance exposure, or other conditions (Tronick & Lester, 2013). Scores are used to recommend appropriate interventions and to guide parents in meeting their baby's unique needs.

The NBAS has been given to many infants around the world. As a result, researchers have learned about individual and cultural differences in newborn behavior and how child-rearing practices can maintain or change a baby's reactions. For example, compared with scores of European-American infants, NBAS scores of Asian and Native-American babies reveal less irritability. Mothers in these cultures often encourage their babies' calm dispositions through holding and nursing at the first signs of discomfort (Muret-Wagstaff & Moore, 1989; Small, 1998). The Kipsigis of rural Kenya, who highly value infant motor maturity, massage babies regularly and begin exercising the stepping reflex shortly after birth. These customs contribute to Kipsigis babies' strong but flexible muscle tone at 5 days of age (Super & Harkness, 2009). In Zambia, Africa, close mother–infant contact throughout the day quickly changes the poor NBAS scores of undernourished newborns. When reassessed at 1 week of age, a once unresponsive newborn appears alert and contented (Brazelton, Koslowski, & Tronick, 1976).

Because newborn behavior and parenting combine to influence development, *changes in scores* over the first week or two of life (rather than a single score) provide the best estimate of the baby's ability to recover from the stress of birth. NBAS “recovery curves” predict intelligence and absence of emotional and behavior problems with moderate success well into the preschool

© JEFFREY L. ROTMAN/CORBIS

Similar to women in the Zambian culture, this mother of the El Molo people of northern Kenya carries her baby all day, providing close physical contact, a rich variety of stimulation, and ready feeding.

years (Brazelton, Nugent, & Lester, 1987; Ohgi et al., 2003a, 2003b).

In some hospitals, health professionals use the NBAS or the NNS to help parents get to know their newborns through discussion or demonstration of the capacities these instruments assess. Parents who participate in these programs, compared with no-intervention controls, interact more confidently and effectively with their babies (Browne & Talmi, 2005; Bruschiweiler-Stern, 2004). Although lasting effects on development have not been demonstrated, NBAS-based interventions are useful in helping the parent–infant relationship get off to a good start.

## Ask yourself

**CONNECT** How do the diverse capacities of newborn babies contribute to their first social relationships? Provide as many examples as you can.

**APPLY** After a difficult delivery, Jackie observes her 2-day-old daughter, Kelly, being given the NBAS. Kelly scores poorly on many items. Seeing this, Jackie wonders if Kelly will develop normally. How would you respond to Jackie's concern?

**REFLECT** Are newborns more competent than you thought they were before you read this chapter? Which of their capacities most surprised you?

## Adjusting to the New Family Unit

**3.12** Describe typical changes in the family after the birth of a baby.

Because effective caregiving is crucial for infant survival and optimal development, nature helps prepare expectant mothers and fathers for their new role. Toward the end of pregnancy, mothers begin producing higher levels of the hormone *oxytocin*, which stimulates uterine contractions; causes the breasts to “let down” milk; induces a calm, relaxed mood; and promotes responsiveness to the baby (Gordon et al., 2010).

Fathers show hormonal changes around the time of birth that are compatible with those of mothers—specifically, slight increases in *prolactin* (a hormone that stimulates milk production in females) and *estrogens* (sex hormones produced in larger quantities in females) and a drop in *androgens* (sex hormones produced in larger quantities in males) (Delahunty et al., 2007; Wynne-Edwards, 2001). These changes, which are induced by fathers’ contact with the mother and baby, predict positive emotional reactions and sensitivity to infants (Feldman et al., 2010; Leuner, Glasper, & Gould, 2010).

Although birth-related hormones can facilitate caregiving, their release and effects seem to depend on experiences, such as a positive couple relationship. Furthermore, as successful adoption reveals, humans can parent effectively without experiencing birth-related hormonal changes. In fact, when foster and adoptive mothers hold and interact with their nonbiological infants, they typically release oxytocin (Bick et al., 2013; Galbally et al., 2011). And the greater their oxytocin production, the more they express affection and pleasure toward the infant.

Nevertheless, the early weeks after a baby’s arrival are full of profound challenges. The mother needs to recover from childbirth. If she is breastfeeding, energies must be devoted to working out this intimate relationship. The father must become a part of this new threesome while supporting the mother in her recovery. At times, he may feel ambivalent about the baby, who constantly demands and gets the mother’s attention. And as we will see in Chapter 6, siblings—especially those who are young and firstborn—understandably feel displaced. They sometimes react with jealousy and anger.

While all this is going on, the tiny infant is assertive about his urgent physical needs, demanding to be fed, changed, and comforted at odd times of the day and night. The family schedule becomes irregular and uncertain, and parental sleep deprivation and consequent daytime fatigue are often major challenges (Insana & Montgomery-Downs, 2012). Yolanda spoke candidly about the changes she and Jay experienced:

When we brought Joshua home, he seemed so small and helpless, and we worried about whether we would be able to take proper care of him. It took us 20 minutes to change the first diaper! I rarely feel rested because I’m up two to four times every night, and I spend a good part of my waking hours trying to anticipate Joshua’s rhythms and needs. If Jay weren’t so willing to help by holding and walking Joshua, I think I’d find it much harder.

In Chapter 14, we will see that when parents’ relationship is positive and cooperative, social support is available, and families have sufficient income, the stress caused by the birth of a baby remains manageable. These family conditions consistently contribute to favorable development—in infancy and beyond.

## Summary / chapter 3

### Prenatal Development (p. 76)

**3.1** List the three periods of prenatal development, and describe the major milestones of each.

- The **germinal period** lasts about two weeks, from fertilization through **implantation** of the multicelled blastocyst in the uterine lining. Structures that will support prenatal growth begin to form, including the **placenta** and the **umbilical cord**.
- During the period of the **embryo**, weeks 2 through 8, the foundations for all body structures are laid down. The **neural tube** forms and the nervous system starts to develop. Other organs follow rapidly. By the end of this period, the embryo responds to touch and can move.
- The period of the **fetus**, lasting until the end of pregnancy, involves dramatic increase in body size and completion of physical structures. High fetal activity in the middle of the second **trimester** strengthens joints and muscles. At the end of the second trimester, most of the brain’s neurons are in place.
- The fetus reaches the **age of viability** at the beginning of the third trimester, between 22 and 26 weeks. The brain continues to develop rapidly, and new sensory and behavioral capacities emerge, including taste and odor preferences, pain sensitivity, and the ability to distinguish the tone and rhythm of different voices and sounds. Gradually the lungs mature, the fetus fills the uterus, and birth is near.

### Prenatal Environmental Influences (p. 81)

**3.2** Cite factors that influence the impact of teratogens, and discuss evidence on the impact of known or suspected teratogens.

- The impact of **teratogens** varies with amount and length of exposure, genetic makeup of mother and fetus, presence of other harmful agents, and age of the organism. The developing organism is especially vulnerable during the embryonic period.
- The most widely used potent teratogen is isotretinoin, a drug used to treat severe acne. The prenatal impact of other commonly used medications, such as aspirin and caffeine, is hard to separate from other correlated factors.

- Babies born to users of cocaine, heroin, or methadone are at risk for a wide variety of problems, including prematurity, low birth weight, brain abnormalities, physical defects, breathing difficulties, and infant death around the time of birth. However, negative effects of cocaine are not well-established.
- Infants whose parents use tobacco are often born underweight, may have physical defects, and are at risk for long-term attention, learning, and behavior problems. Maternal alcohol consumption can lead to **fetal alcohol spectrum disorder (FASD)**. **Fetal alcohol syndrome (FAS)**, resulting from heavy drinking throughout pregnancy, involves slow physical growth, facial abnormalities, and mental impairments. Milder forms—**partial fetal alcohol syndrome (p-FAS)** and **alcohol-related neurodevelopmental disorder (ARND)**—affect children whose mothers consumed smaller quantities of alcohol.
- Prenatal exposure to high levels of ionizing radiation, mercury, PCBs, lead, and dioxins leads to physical malformations and severe brain damage. Low-level exposure has been linked to cognitive deficits and emotional and behavioral disorders. Persistent air pollution is associated with low birth weight and impaired lung and immune-system functioning.

ROSILAN RAHMAN/AFP/GETTY IMAGES

- Among infectious diseases, rubella causes wide-ranging abnormalities. Babies with prenatally transmitted HIV rapidly develop AIDS, leading to brain damage and early death. Antiretroviral drug therapy dramatically reduces prenatal transmission. Cytomegalovirus, herpes simplex 2, and toxoplasmosis can also be devastating to the embryo and fetus.

### 3.3 Describe the impact of additional maternal factors on prenatal development.

- Exercise during pregnancy is linked to improved fetal cardiovascular functioning and reduction in risk of pregnancy complications.
- Prenatal malnutrition can lead to low birth weight, damage to the brain and other organs, and suppression of immune system development. Vitamin–mineral supplementation, including folic acid, can prevent prenatal and birth complications.
- Severe emotional stress is linked to pregnancy complications and may permanently alter fetal neurological functioning, resulting in impaired capacity to manage stress and susceptibility to later illness. Stress-related prenatal consequences can be reduced by providing the mother with social support. **Rh factor incompatibility**—an Rh-positive fetus developing within an Rh-negative mother—can lead to oxygen deprivation, brain and heart damage, and infant death.
- Older mothers face increased risk of miscarriage, babies with chromosomal defects, and, after age 40, a rise in other pregnancy complications. Poor health and environmental risks associated with poverty explain higher rates of pregnancy complications in adolescent mothers.

### 3.4 Why is early and regular health care vital during the prenatal period?

- Unexpected difficulties, such as preeclampsia, can arise, especially when pregnant women have preexisting health problems. Prenatal health care is especially crucial for women least likely to seek it, particularly those who are young, less-educated, and low-income.

## Childbirth (p. 92)

### 3.5 Describe the three stages of childbirth, the baby's adaptation to labor and delivery, and the newborn baby's appearance.

- In the first stage, contractions widen and thin the cervix. In the second stage, the mother feels an urge to push the baby through the birth canal. In the final stage, the placenta is delivered. During labor, infants produce high levels of stress hormones, which help them withstand oxygen deprivation, clear the lungs for breathing, and arouse them into alertness at birth.
- Newborn babies have large heads, small bodies, and facial features that make adults feel like cuddling them. The **Apgar Scale** assesses the baby's physical condition at birth.

## Approaches to Childbirth (p. 95)

### 3.6 Describe natural childbirth and home delivery, noting benefits and concerns associated with each.

- In **natural**, or **prepared, childbirth**, the expectant mother and a companion attend classes about labor and delivery, master relaxation and breathing techniques to counteract pain, and prepare for coaching during childbirth. Social support from a doula reduces the length of labor and the incidence of birth complications and enhances newborn adjustment.

ANDERSEN ROSS/BRAND X PICTURES/GETTY IMAGES

- Home birth is safe for healthy mothers who are assisted by a well-trained doctor or midwife, but mothers at risk for complications are safer giving birth in a hospital.

## Medical Interventions (p. 96)

### 3.7 List common medical interventions during childbirth, circumstances that justify their use, and any dangers associated with each.

- **Fetal monitors** help save the lives of many babies at risk for **anoxia** because of pregnancy and birth complications. When used routinely, however, they may identify infants as in danger who, in fact, are not.
- Use of analgesics and anesthetics to control pain, though necessary in complicated deliveries, can prolong labor and may have negative effects on newborn adjustment.
- **Cesarean delivery** is warranted by medical emergency or serious maternal illness and for many babies who are in **breech position**. However, many unnecessary cesareans are performed.

## Preterm and Low-Birth-Weight Infants (p. 97)

### 3.8 Describe risks associated with preterm birth and low birth weight, along with effective interventions.

- Low birth weight, most common in infants born to poverty-stricken women, is a major cause of neonatal and **infant mortality** and developmental problems. Compared with **preterm infants**, whose weight is appropriate for time spent in the uterus, **small-for-date infants** usually have longer-lasting difficulties.
- Some interventions provide special infant stimulation in the intensive care nursery. Others teach parents how to care for and interact with their babies. Preterm infants in stressed, low-income households need long-term, intensive intervention.

© PICTURE PARTNERS/ALAMY

## The Newborn Baby's Capacities (p. 101)

### 3.9 Describe the newborn baby's reflexes and states of arousal, noting sleep characteristics and ways to soothe a crying baby.

- **Reflexes** are the newborn baby's most obvious organized patterns of behavior. Some have survival value, others help parents and infants establish gratifying interaction, and a few provide the foundation for complex motor skills.

- Newborns experience five **states of arousal** but spend most of their time asleep. Sleep includes at least two states, **rapid-eye-movement (REM) sleep** and **non-rapid-eye-movement (NREM) sleep**. Newborns spend about 50 percent of sleep time in REM sleep, which provides them with stimulation essential for central nervous system development.

© DAVID POOLE/ROBERT HARDING

- A crying baby stimulates strong feelings of discomfort in nearby adults. Once feeding and diaper changing have been tried, a highly effective soothing technique is lifting the baby to the shoulder and rocking or walking. Extensive parent–infant physical contact substantially reduces crying in the early months.

### 3.10 Describe the newborn baby's sensory capacities.

- The senses of touch, taste, smell, and sound are well-developed at birth. Newborns use touch to investigate their world, are sensitive to pain, prefer sweet tastes and smells, and orient toward the odor of their own mother's lactating breast.
- Newborns can distinguish a variety of sound patterns and prefer complex sounds. They are especially responsive to human speech, can detect the sounds of any human language, and prefer their mother's voice.

- Vision is the least developed of the newborn's senses. At birth, focusing ability and **visual acuity** are limited. In exploring the visual field, newborn babies are attracted to bright objects but have difficulty discriminating colors.

### 3.11 Why is neonatal behavioral assessment useful?

- The most widely used instrument for assessing the newborn infant's behavior, Brazelton's **Neonatal Behavioral Assessment Scale (NBAS)**, has helped researchers understand individual and cultural differences in newborn behavior. Sometimes it is used to teach parents about their baby's capacities.

## Adjusting to the New Family Unit (p. 111)

### 3.12 Describe typical changes in the family after the birth of a baby.

- The new baby's arrival is exciting but stressful, as the mother recuperates from childbirth and the family schedule becomes irregular and uncertain. When parents have a positive relationship as well as social support and adequate income, adjustment problems are usually temporary.

## Physical Development in Infancy and Toddlerhood

Beginning to walk frees this 14-month-old's hands for carrying objects, grants a whole new perspective on a tantalizing physical world to explore, and enables her to interact with caregivers in new ways—for example, by showing an object or giving a hug. In the first two years, motor, perceptual, cognitive, and social development mutually influence one another.

■ **BIOLOGY AND ENVIRONMENT** “Tuning In” to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning

On a brilliant June morning, 16-month-old Caitlin emerged from her front door, ready for the short drive to the child-care home where she spent her weekdays while her mother, Carolyn, and her father, David, worked. Clutching a teddy bear in one hand and her mother's arm with

the other, Caitlin descended the steps. “One! Two! Threeee!” Carolyn counted as she helped Caitlin down. “How much she's changed,” Carolyn thought to herself, looking at the child who, not long ago, had been a newborn. With her first steps, Caitlin had passed from *infancy* to *toddlerhood*—a period spanning the second year of life. At first, Caitlin did, indeed, “toddle” with an awkward gait, tipping over frequently. But her face reflected the thrill of conquering a new skill.

As they walked toward the car, Carolyn and Caitlin spotted 3-year-old Eli and his father, Kevin, in the neighboring yard. Eli dashed toward them, waving a bright yellow envelope. Carolyn bent down to open the envelope and took out a card. It read, “Announcing the arrival of Grace Ann. Born: Cambodia. Age: 16 months.” Carolyn turned to Kevin and Eli. “That's wonderful news! When can we see her?”

“Let's wait a few days,” Kevin suggested. “Monica's taken Grace to the doctor this morning. She's underweight and malnourished.” Kevin described Monica's first night with Grace in a hotel room in Phnom Penh. Grace lay on the bed, withdrawn and fearful. Eventually she fell asleep, gripping crackers in both hands.

Carolyn felt Caitlin's impatient tug at her sleeve. Off they drove to child care, where Vanessa had just dropped off her 18-month-old son, Timmy. Within moments, Caitlin and Timmy were in the sandbox, shoveling sand into plastic cups and buckets with the help of their caregiver, Ginette.

A few weeks later, Grace joined Caitlin and Timmy at Ginette's child-care home. Although still tiny and unable to crawl or walk, she had grown taller and heavier, and her sad, vacant gaze had given way to an alert expression, a ready smile, and an enthusiastic desire to imitate and explore. When Caitlin headed for the sandbox, Grace stretched out her arms, asking Ginette to carry her there, too. Soon Grace was pulling herself up at every opportunity. Finally, at age 18 months, she walked!

This chapter traces physical growth during the first two years—one of the most remarkable and busiest times of development. We will see how rapid changes in the infant's body and brain support learning, motor skills, and perceptual capacities. Caitlin, Grace, and Timmy will join us along the way to illustrate individual differences and environmental influences on physical development. ●

## Body Growth

### 4.1 Describe major changes in body growth over the first two years.

The next time you're walking in your neighborhood park or at the mall, note the contrast between infants' and toddlers' physical capabilities. One reason for the vast changes in what children can do over the first two years is that their bodies change enormously—faster than at any other time after birth.

## Changes in Body Size and Muscle–Fat Makeup

By the end of the first year, a typical infant's height is about 32 inches—more than 50 percent greater than at birth. By 2 years, it is 75 percent greater (36 inches). Similarly, by 5 months of age, birth weight has doubled, to about 15 pounds. At 1 year it has tripled, to 22 pounds, and at 2 years it has quadrupled, to about 30 pounds.

Figure 4.1 illustrates this dramatic increase in body size. But rather than making steady gains, infants and toddlers grow in

**FIGURE 4.1** Body growth during the first two years. These photos depict the dramatic changes in body size and proportions during infancy and toddlerhood in two individuals—a boy, Shanwel, and a girl, Mai. In the first year, the head is quite large in proportion to the rest of the body, and height and weight gain are especially rapid. During the second year, the lower portion of the body catches up. Notice, also, how both children added “baby fat” in the early months of life and then slimmed down, a trend that continues into middle childhood.

little spurts. In one study, children who were followed over the first 21 months of life went for periods of 7 to 63 days with no growth, then added as much as half an inch in a 24-hour period! Almost always, parents described their babies as irritable, very hungry, and sleeping more on the days before the spurt (Lampl, 1993; Lampl & Johnson, 2011).

One of the most obvious changes in infants' appearance is their transformation into round, plump babies by the middle of the first year. This early rise in "baby fat," which peaks at about 9 months, helps the small infant maintain a constant body temperature. In the second year, most toddlers slim down, a trend that continues into middle childhood (Fomon & Nelson, 2002). In contrast, muscle tissue increases very slowly during infancy and will not reach a peak until adolescence. Babies are not very muscular; their strength and physical coordination are limited.

## Changes in Body Proportions

As the child's overall size increases, different parts of the body grow at different rates. Two growth patterns describe these changes. The first is the **cephalocaudal trend**—from the Latin for "head to tail." During the prenatal period, the head develops more rapidly than the lower part of the body. At birth, the head takes up one-fourth of total body length, the legs only one-third. Notice how, in Figure 4.1, the lower portion of the body catches up. By age 2, the head accounts for only one-fifth and the legs for nearly one-half of total body length.

In the second pattern, the **proximodistal trend**, growth proceeds, literally, from "near to far"—from the center of the body outward. In the prenatal period, the head, chest, and trunk grow first; then the arms and legs; and finally the hands and feet. During infancy and childhood, the arms and legs continue to grow somewhat ahead of the hands and feet.

## Individual and Group Differences

In infancy, girls are slightly shorter and lighter than boys, with a higher ratio of fat to muscle. These small sex differences persist throughout early and middle childhood and are greatly magnified at adolescence. Ethnic differences in body size are apparent as well. Grace was below the *growth norms* (height and weight averages for children her age). Early malnutrition contributed, but even after substantial catch-up, Grace—as is typical for Asian children—remained below North American norms. In contrast, Timmy is slightly above average, as African-American children tend to be (Bogin, 2001).

Children of the same age differ in *rate* of physical growth; some make faster progress toward a mature body size than others. But current body size is not enough to tell us how quickly a child's physical growth is moving along. Although Timmy is larger and heavier than Caitlin and Grace, he is not physically more mature. In a moment, you will see why.

The best estimate of a child's physical maturity is *skeletal age*, a measure of bone development. It is determined by X-raying

the long bones of the body to see the extent to which soft, pliable cartilage has hardened into bone—a gradual process that is completed in adolescence. When skeletal ages are examined, African-American children tend to be slightly ahead of European-American children, and girls are considerably ahead of boys. At birth, the sexes differ by about 4 to 6 weeks, a gap that widens over infancy and childhood (Tanner, Healy, & Cameron, 2001). Girls are advanced in development of other organs as well. This greater physical maturity may contribute to girls' greater resistance to harmful environmental influences. As noted in Chapter 2, girls experience fewer developmental problems than boys and have lower infant and childhood mortality rates.

## Brain Development

**4.2** Describe brain development during infancy and toddlerhood, current methods of measuring brain functioning, and appropriate stimulation to support the brain's potential.

**4.3** How does the organization of sleep and wakefulness change over the first two years?

At birth, the brain is nearer to its adult size than any other physical structure, and it continues to develop at an astounding pace throughout infancy and toddlerhood. We can best understand brain growth by looking at it from two vantage points: (1) the microscopic level of individual brain cells and (2) the larger level of the cerebral cortex, the most complex brain structure and the one responsible for the highly developed intelligence of our species.

## Development of Neurons

The human brain has 100 to 200 billion **neurons**, or nerve cells, that store and transmit information, many of which have thousands of direct connections with other neurons. Unlike other body cells, neurons are not tightly packed together. Between them are tiny gaps, or **synapses**, where fibers from different neurons come close together but do not touch (see Figure 4.2 on page 118). Neurons send messages to one another by releasing chemicals called **neurotransmitters**, which cross the synapse.

The basic story of brain growth concerns how neurons develop and form this elaborate communication system. Figure 4.3 on page 118 summarizes major milestones of brain development. In the prenatal period, neurons are produced in the embryo's primitive neural tube. From there, they migrate to form the major parts of the brain (see Chapter 3, page 79). Once neurons are in place, they differentiate, establishing their unique functions by extending their fibers to form synaptic connections with neighboring cells. During the first two years, neural fibers and synapses increase at an astounding pace (Gilmore et al., 2012; Moore, Persaud, & Torchia, 2016a). A surprising aspect of brain growth

© ASAP/CNRI/SCIENCE SOURCE/PHOTO RESEARCHERS, INC.

**FIGURE 4.2 Neurons and their connective fibers.** This photograph of several neurons, taken with the aid of a powerful microscope, shows the elaborate synaptic connections that form with neighboring cells.

is **programmed cell death**, which makes space for these connective structures: As synapses form, many surrounding neurons die—40 to 60 percent, depending on the brain region (Jabès & Nelson, 2014). Fortunately, during the prenatal period, the neural tube produces far more neurons than the brain will ever need.

As neurons form connections, *stimulation* becomes vital to their survival. Neurons that are stimulated by input from the surrounding environment continue to establish new synapses, forming increasingly elaborate systems of communication that support more complex abilities. At first, stimulation results in a massive overabundance of synapses, many of which serve identical functions, thereby ensuring that the child will acquire the motor, cognitive, and social skills that our species needs to survive. Neurons that are seldom stimulated soon lose their synapses, in a process called **synaptic pruning** that returns neurons not needed at the moment to an uncommitted state so they can support future development. In all, about 40 percent of synapses are pruned during childhood and adolescence to reach the adult level (Webb, Monk, & Nelson, 2001). For this process to advance, appropriate stimulation of the child's brain is vital during periods in which the formation of synapses is at its peak (Bryk & Fisher, 2012).

If few neurons are produced after the prenatal period, what causes the extraordinary increase in brain size during the first two years? About half the brain's volume is made up of **glial cells**, which are responsible for **myelination**, the coating of neural fibers with an insulating fatty sheath (called *myelin*) that improves the efficiency of message transfer. Glial cells multiply rapidly from the end of pregnancy through the second year of life—a process that continues at a slower pace through middle childhood and accelerates again in adolescence. Gains in neural fibers and myelination account for the overall increase in size of the brain, from nearly 30 percent of its adult weight at birth to 70 percent by age 2 (Johnson, 2011). Growth is especially dramatic during the first year, when the brain more than doubles in size.

**FIGURE 4.3 Major milestones of brain development.** Formation of synapses is rapid during the first two years, especially in the auditory, visual, and language areas of the cerebral cortex. The prefrontal cortex, responsible for complex thought (see page 120), undergoes more extended synaptic growth. In each area, overproduction of synapses is followed by synaptic pruning. The prefrontal cortex is among the last regions to attain adult levels of synaptic connections—in mid- to late adolescence. Myelination occurs at a dramatic pace during the first two years, more slowly through childhood, followed by an acceleration at adolescence and then a reduced pace in early adulthood. The multiple yellow lines indicate that the timing of myelination varies among different brain areas. For example, neural fibers myelinate over a longer period in the language areas, and especially in the prefrontal cortex, than in the visual and auditory areas. (Based on Thompson & Nelson, 2001.)

Brain development can be compared to molding a “living sculpture.” First, neurons and synapses are overproduced. Then, cell death and synaptic pruning sculpt away excess building material to form the mature brain—a process jointly influenced by genetically programmed events and the child’s experiences. The resulting “sculpture” is a set of interconnected regions, each with specific functions—much like countries on a globe that communicate with one another (Johnston et al., 2001). This “geography” of the brain permits researchers to study its organization and the activity of its regions using neurobiological techniques.

## Measures of Brain Functioning

Table 4.1 describes major measures of brain functioning. Among these methods, the two most frequently used detect changes in *electrical activity* in the cerebral cortex. In an *electroencephalogram (EEG)*, researchers examine *brain-wave patterns* for stability and organization—signs of mature functioning of the cortex. And as the person processes a particular stimulus, *event-related potentials (ERPs)* detect the general location of brain-wave activity—a technique often used to study preverbal infants’ responsiveness to various stimuli, the impact of experience on specialization of specific regions of the cortex, and atypical brain functioning in individuals with learning and emotional problems (DeBoer, Scott, & Nelson, 2007; Gunnar & de Haan, 2009).

*Neuroimaging techniques*, which yield detailed, three-dimensional computerized pictures of the entire brain and its

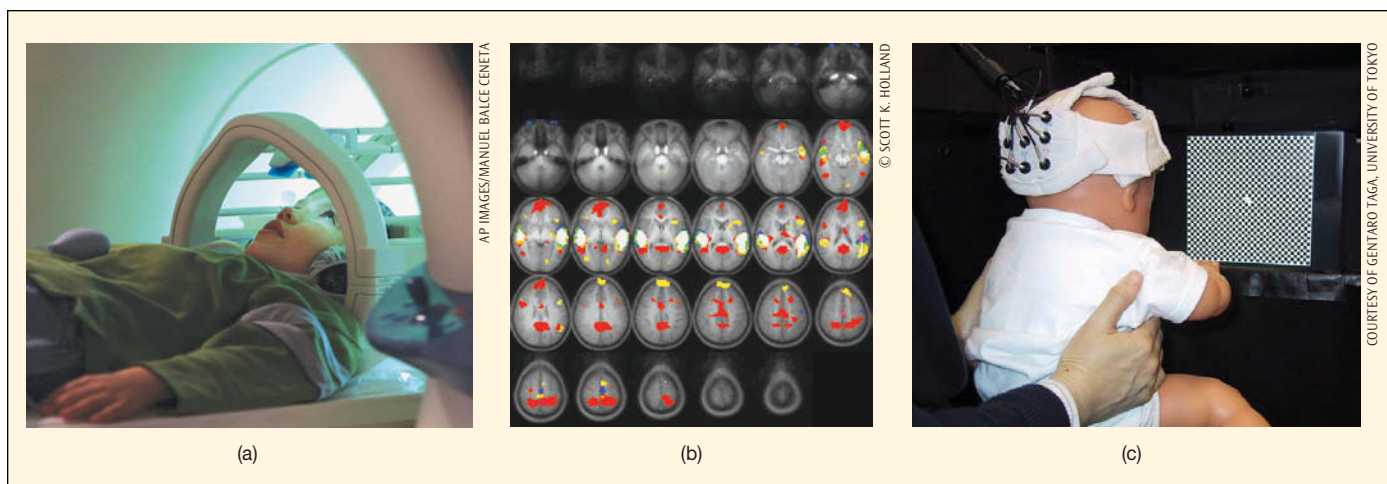

active areas, provide the most precise information about which brain regions are specialized for certain capacities and about abnormalities in brain functioning. The most promising of these methods is *functional magnetic resonance imaging (fMRI)*. Unlike *positron emission tomography (PET)*, fMRI does not depend on X-ray photography, which requires injection of a radioactive substance. Rather, when an individual is exposed to a stimulus, fMRI detects changes in blood flow and oxygen metabolism throughout the brain magnetically, yielding a colorful, moving picture of parts of the brain used to perform a given activity (see Figure 4.4a and b on page 120).

Because PET and fMRI require that the participant lie as motionless as possible for an extended time, they are not suitable for infants and young children. A neuroimaging technique that works well in infancy and early childhood is *near-infrared spectroscopy (NIRS)*, in which infrared (invisible) light is beamed at regions of the cerebral cortex to measure blood flow and oxygen metabolism while the child attends to a stimulus (refer again to Table 4.1). Because the apparatus consists only of thin, flexible optical fibers attached to the scalp using a head cap, a baby can sit on the parent’s lap and move during testing—as Figure 4.4c illustrates (Hespos et al., 2010). But unlike PET and fMRI, which map activity changes throughout the brain, NIRS examines only the functioning of the cerebral cortex.

The measures just reviewed are powerful tools for uncovering relationships between the brain and psychological development. But like all research methods, they have limitations. Even

**TABLE 4.1**  
**Measuring Brain Functioning**

METHOD	DESCRIPTION
Electroencephalogram (EEG)	Electrodes embedded in a head cap record electrical brain-wave activity in the brain’s outer layers—the cerebral cortex. Researchers use an advanced tool called a geodesic sensor net (GSN) to hold interconnected electrodes (up to 128 for infants and 256 for children and adults) in place through a cap that adjusts to each person’s head shape, yielding improved brain-wave detection.
Event-related potentials (ERPs)	Using the EEG, the frequency and amplitude of brain waves in response to particular stimuli (such as a picture, music, or speech) are recorded in the cerebral cortex. Enables identification of general regions of stimulus-induced activity.
Functional magnetic resonance imaging (fMRI)	While the person lies inside a tunnel-shaped apparatus that creates a magnetic field, a scanner magnetically detects increased blood flow and oxygen metabolism in areas of the brain as the individual processes particular stimuli. The scanner typically records images every 1 to 4 seconds; these are combined into a computerized moving picture of activity anywhere in the brain (not just its outer layers). Not appropriate for children younger than ages 5 to 6, who cannot remain still during testing.
Positron emission tomography (PET)	After injection or inhalation of a radioactive substance, the person lies on an apparatus with a scanner that emits fine streams of X-rays, which detect increased blood flow and oxygen metabolism in areas of the brain as the person processes particular stimuli. As with fMRI, the result is a computerized image of activity anywhere in the brain. Not appropriate for children younger than ages 5 to 6.
Near-infrared spectroscopy (NIRS)	Using thin, flexible optical fibers attached to the scalp through a head cap, infrared (invisible) light is beamed at the brain; its absorption by areas of the cerebral cortex varies with changes in blood flow and oxygen metabolism as the individual processes particular stimuli. The result is a computerized moving picture of active areas in the cerebral cortex. Unlike fMRI and PET, NIRS is appropriate for infants and young children, who can move within a limited range during testing.

**FIGURE 4.4 Functional magnetic resonance imaging (fMRI) and near-infrared spectroscopy (NIRS).** (a) This 6-year-old is part of a study that uses fMRI to find out how his brain processes light and motion. (b) The fMRI image shows which areas of the child's brain are active while he views changing visual stimuli. (c) Here, NIRS is used to investigate a 2-month-old's response to a visual stimulus. During testing, the baby can move freely within a limited range. (Photo [c] from G. Taga, K. Asakawa, A. Maki, Y. Konishi, & H. Koisumi, 2003, "Brain Imaging in Awake Infants by Near-Infrared Optical Topography," *Proceedings of the National Academy of Sciences*, 100, p. 10723. Reprinted by permission.)

though a stimulus produces a consistent pattern of brain activity, investigators cannot be certain that an individual has processed it in a certain way (Kagan, 2013b). And a researcher who takes a change in brain activity as an indicator of information processing must make sure that the change was not due instead to hunger, boredom, fatigue, or body movements. Consequently, other methods must be combined with brain-wave and -imaging findings to clarify their meaning (de Haan & Gunnar, 2009). Now let's turn to the developing organization of the cerebral cortex.

## Development of the Cerebral Cortex

The **cerebral cortex** surrounds the rest of the brain, resembling half of a shelled walnut. It is the largest brain structure, accounting for 85 percent of the brain's weight and containing the greatest number of neurons and synapses. Because the cerebral cortex is the last part of the brain to stop growing, it is sensitive to environmental influences for a much longer period than any other part of the brain.

**Regions of the Cerebral Cortex.** Figure 4.5 shows specific functions of regions of the cerebral cortex, such as receiving information from the senses, instructing the body to move, and thinking. The order in which cortical regions develop corresponds to the order in which various capacities emerge in the infant and growing child. For example, a burst of activity occurs in the auditory and visual cortices and in areas responsible for body movement over the first year—a period of dramatic gains in auditory and visual perception and mastery of motor skills (Gilmore et al., 2012). Language areas are especially active from late infancy through the preschool years, when language development flourishes (Pujol et al., 2006).

The cortical regions with the most extended period of development are the *frontal lobes*. The **prefrontal cortex**, lying in front of areas controlling body movement, is responsible for complex thought—in particular, consciousness and various “executive” processes, including inhibition of impulses, integration of information, and memory, reasoning, planning, and problem-solving strategies. From age 2 months on, the prefrontal cortex functions more effectively. But it undergoes especially rapid myelination and formation and pruning of synapses during the preschool and school years, followed by another period of accel-

**FIGURE 4.5 The left side of the human brain, showing the cerebral cortex.** The cortex is divided into different lobes, each of which contains a variety of regions with specific functions. Some major regions are labeled here.

erated growth in adolescence, when it reaches an adult level of synaptic connections (Jabès & Nelson, 2014; Nelson, Thomas, & de Haan, 2006).

**Lateralization and Plasticity of the Cortex.** The cerebral cortex has two *hemispheres*, or sides, that differ in their functions. Some tasks are done mostly by the left hemisphere, others by the right. For example, each hemisphere receives sensory information from the side of the body opposite to it and controls only that side.\* For most of us, the left hemisphere is largely responsible for verbal abilities (such as spoken and written language) and positive emotion (such as joy). The right hemisphere handles spatial abilities (judging distances, reading maps, and recognizing geometric shapes) and negative emotion (such as distress) (Banish & Heller, 1998; Nelson & Bosquet, 2000). In left-handed people, this pattern may be reversed or, more commonly, the cerebral cortex may be less clearly specialized than in right-handers.

Why does this specialization of the two hemispheres, called **lateralization**, occur? Studies using fMRI reveal that the left hemisphere is better at processing information in a sequential, analytic (piece-by-piece) way, a good approach for dealing with communicative information—both verbal (language) and emotional (a joyful smile). In contrast, the right hemisphere is specialized for processing information in a holistic, integrative manner, ideal for making sense of spatial information and regulating negative emotion. A lateralized brain may have evolved because it enabled humans to cope more successfully with changing environmental demands (Falk, 2005). It permits a wider array of functions to be carried out effectively than if both sides processed information in exactly the same way.

Researchers study the timing of brain lateralization to learn more about **brain plasticity**. A highly *plastic* cerebral cortex, in which many areas are not yet committed to specific functions, has a high capacity for learning. And if a part of the cortex is damaged, other parts can take over tasks it would have handled. But once the hemispheres lateralize, damage to a specific region means that the abilities it controls cannot be recovered to the same extent or as easily as earlier.

At birth, the hemispheres have already begun to specialize. Most newborns show greater activation (detected with either ERP or NIRS) in the left hemisphere while listening to speech sounds or displaying a positive state of arousal. In contrast, the right hemisphere reacts more strongly to nonspeech sounds and to stimuli (such as a sour-tasting fluid) that evoke negative emotion (Fox & Davidson, 1986; Hespos et al., 2010).

Nevertheless, research on brain-damaged children and adults offers evidence for substantial plasticity in the young brain, summarized in the Biology and Environment box on page 122. Furthermore, early experience greatly influences the organization of the cerebral cortex. For example, deaf adults who, as infants

and children, learned sign language (a spatial skill) depend more than hearing individuals on the right hemisphere for language processing (Neville & Bavelier, 2002). And toddlers who are advanced in language development show greater left-hemispheric specialization for language than their more slowly developing age mates (Luna et al., 2001; Mills et al., 2005). Apparently, the very process of acquiring language and other skills promotes lateralization.

In sum, the brain is more plastic during the first few years than at later ages. An overabundance of synaptic connections supports brain plasticity and, therefore, young children's ability to learn, which is fundamental to their survival (Murphy & Corbett, 2009). And although the cortex is programmed from the start for hemispheric specialization, experience greatly influences the rate and success of its advancing organization.

## Sensitive Periods in Brain Development

Animal studies confirm that early, extreme sensory deprivation results in permanent brain damage and loss of functions—findings that verify the existence of sensitive periods in brain development. For example, early, varied visual experiences must occur for the brain's visual centers to develop normally. If a 1-month-old kitten is deprived of light for just 3 or 4 days, these areas of the brain degenerate. If the kitten is kept in the dark during the fourth week of life and beyond, the damage is severe and permanent (Crair, Gillespie, & Stryker, 1998). And the general quality of the early environment affects overall brain growth. When animals reared from birth in physically and socially stimulating surroundings are compared with those reared in isolation, the brains of the stimulated animals are larger and show much denser synaptic connections (Sale, Berardi, & Maffei, 2009).

**Human Evidence: Victims of Deprived Early Environments.** For ethical reasons, we cannot deliberately deprive some infants of normal rearing experiences and observe the impact on their brains and competencies. Instead, we must turn to natural experiments, in which children were victims of deprived early environments that were later rectified. Such studies have revealed some parallels with the animal evidence just described.

For example, when babies are born with cataracts in both eyes (clouded lenses, preventing clear visual images), those who have corrective surgery within 4 to 6 months show rapid improvement in vision, except for subtle aspects of face perception, which require early visual input to the right hemisphere to develop (Maurer & Lewis, 2013; Maurer, Mondloch, & Lewis, 2007). The longer cataract surgery is postponed beyond infancy, the less complete the recovery in visual skills. And if surgery is delayed until adulthood, vision is severely and permanently impaired (Lewis & Maurer, 2005).

Studies of infants placed in orphanages who were later exposed to ordinary family rearing confirm the importance of a generally stimulating environment for psychological development. In one investigation, researchers followed the progress of a

\* The eyes are an exception. Messages from the right half of each retina go to the right hemisphere; messages from the left half of each retina go to the left hemisphere. Thus, visual information from both eyes is received by both hemispheres.

## Biology and Environment

### Brain Plasticity: Insights from Research on Brain-Damaged Children and Adults

In the first few years of life, the brain is highly plastic. It can reorganize areas committed to specific functions in a way that the mature brain cannot. Adults who suffered injury to a part of the brain in infancy and early childhood usually show fewer cognitive impairments than adults with later-occurring injury (Huttenlocher, 2002).

Nevertheless, the young brain is not totally plastic. When it is injured, its functioning is compromised. The extent of plasticity depends on several factors, including age at time of injury, site and severity of damage, skill area, and environmental supports for recovery. Furthermore, plasticity is not restricted to childhood. Some reorganization after injury also occurs in the mature brain.

#### Brain Plasticity in Infancy and Early Childhood

In a large study of children with injuries to the cerebral cortex that occurred around the time of birth or in the first six months of life, language and spatial skills were assessed repeatedly into adolescence (Stiles, Reilly, & Levine, 2012; Stiles et al., 2005, 2008, 2009). All the children had experienced early brain seizures or hemorrhages. Brain-imaging techniques (fMRI and PET) revealed the precise site of damage.

Regardless of whether injury occurred in the left or right cerebral hemisphere, the children showed delays in language development that persisted until about age 3½ years. That damage to either hemisphere affected early language competence indicates that at first, language functioning is broadly distributed in the brain. But by age 5, the children caught up in vocabulary and grammatical skills. Undamaged areas—in either the left or the right hemisphere—had taken over these language functions.

Compared with language, spatial skills were more impaired. When preschool through adolescent-age youngsters were asked to copy designs, those with early right-hemispheric damage had trouble with holistic processing—accurately representing the overall shape. In contrast, children with left-hemispheric

damage captured the basic shape but omitted fine-grained details. Nevertheless, the children improved in their drawing skills with age—gains that did not occur in brain-injured adults (Stiles, Reilly, & Levine, 2012; Stiles et al., 2003, 2008, 2009).

Clearly, recovery after early brain injury is greater for language than for spatial skills. Why is this so? Researchers speculate that spatial processing is the older of the two capacities in our evolutionary history and, therefore, more lateralized at birth (Stiles et al., 2008). But early brain injury has far less impact than later injury on both language and spatial skills, revealing the young brain's plasticity.

#### The Price of High Plasticity in the Young Brain

Despite impressive recovery of language and (to a lesser extent) spatial skills, children with early brain injuries show deficits in a wide range of complex mental abilities during the school years. For example, their reading and math progress is slow. In telling stories, they produce simpler narratives than agetates without early brain injuries. And as the demands of daily life increase, they have difficulty managing homework and other responsibilities (Anderson, Spencer-Smith, & Wood, 2011; Stiles, Reilly, & Levine, 2012).

High brain plasticity, researchers explain, comes at a price. When healthy brain regions take over the functions of damaged areas, a “crowding effect” occurs: Multiple tasks must be done by a smaller-than-usual volume of brain tissue (Stiles, 2012). Complex mental abilities of all kinds suffer because performing them well requires the collaboration of many regions in the cerebral cortex.

#### Brain Plasticity in Adulthood

Brain plasticity is not restricted to early childhood. Though far more limited, reorganization in the brain can occur later, even in adulthood. For example, adult stroke victims often display considerable recovery, especially in response to stimulation of language and motor

KIM GUNKEL/GETTY IMAGES

This preschooler, who experienced brain damage in infancy, has been spared massive impairments because of high plasticity of the brain. Here, a teacher encourages her to cut basic shapes to strengthen spatial skills, which remain more impaired than language after early brain injury.

skills. Brain-imaging findings reveal that structures adjacent to the permanently damaged area or in the opposite cerebral hemisphere reorganize to support the impaired ability (Kalra & Ratan, 2007; Murphy & Corbett, 2009).

In infancy and childhood, the goal of brain growth is to form neural connections that ensure mastery of essential skills. At older ages, specialized brain structures are in place, but after injury they can still reorganize to some degree. The adult brain can produce a small number of new neurons. And when an individual practices relevant tasks, the brain strengthens existing synapses and generates new ones.

Nevertheless, when brain injury is widespread, recovery for both children and adults is greatly reduced. And when damage occurs to certain regions—for example, the prefrontal cortex—recovery is also limited (Pennington, 2015). Because of its executive role in thinking and widespread connections throughout the brain, prefrontal abilities are difficult to transfer to other cortical areas. Consequently, early prefrontal lesions typically result in persisting, general intellectual deficits (Pennington, 2015). Clearly, brain plasticity is a complex process that is not equivalent throughout the brain.

large sample of children transferred between birth and 3½ years from extremely deprived Romanian orphanages to adoptive families in Great Britain (Beckett et al., 2006; O'Connor et al., 2000; Rutter et al., 1998, 2004, 2010). On arrival, most were impaired in all domains of development. Cognitive catch-up was impressive for children adopted before 6 months, who attained average mental test scores in childhood and adolescence, performing as well as a comparison group of early-adopted British-born children.

But Romanian children who had been institutionalized for more than the first six months showed serious intellectual deficits (see Figure 4.6). Although they improved in intelligence test scores during middle childhood and adolescence, they remained substantially below average. And most displayed at least three serious mental health problems, such as inattention, overactivity, unruly behavior, and autistic-like symptoms (social disinterest, stereotyped behavior) (Kreppner et al., 2007, 2010).

Neurobiological findings indicate that early, prolonged institutionalization leads to a generalized decrease in size and activity in the cerebral cortex—especially the prefrontal cortex, which governs complex cognition and impulse control. Neural fibers connecting the prefrontal cortex with other brain structures involved in control of emotion are also reduced (Hodel et al., 2014; McLaughlin et al., 2014; Nelson, 2007). And activation of the left cerebral hemisphere, governing positive emotion, is diminished relative to right cerebral activation, governing negative emotion (McLaughlin et al., 2011).

Additional evidence confirms that the chronic stress of early, deprived orphanage rearing disrupts the brain's capacity to

**FIGURE 4.6** Relationship of age at adoption to mental test scores at ages 6 and 11 among British and Romanian adoptees. Children transferred from Romanian orphanages to British adoptive homes in the first six months of life attained average scores and fared as well as British early-adopted children, suggesting that they had fully recovered from extreme early deprivation. Romanian children adopted after 6 months of age performed well below average. And although those adopted after age 2 improved between ages 6 and 11, they continued to show serious intellectual deficits. (Adapted from Beckett et al., 2006.)

This Romanian orphan receives little adult contact or stimulation. The longer he remains in this barren environment, the greater his risk of brain damage and lasting impairments in all domains of development.

manage stress. In another investigation, researchers followed the development of children who had spent their first eight months or more in Romanian institutions and were then adopted into Canadian homes (Gunnar & Cheatham, 2003; Gunnar et al., 2001). Compared with age-mates adopted shortly after birth, these children showed extreme stress reactivity, as indicated by high concentrations of the stress hormone *cortisol* in their saliva. The longer the children spent in orphanage care, the higher their cortisol levels—even 6½ years after adoption.

In other research, orphanage children from diverse regions of the world who were later adopted by American families displayed abnormally low cortisol—a blunted physiological response that (as we saw in Chapter 3) is also a sign of impaired capacity to manage stress (Koss et al., 2014; Loman & Gunnar, 2010). Persisting abnormally high or low cortisol levels are linked to later learning, emotional, and behavior problems, including both internalizing and externalizing difficulties.

**Appropriate Stimulation.** Unlike the orphanage children just described, Grace, whom Monica and Kevin had adopted from Cambodia at 16 months of age, showed favorable progress. Two years earlier, they had adopted Grace's older brother, Eli. When Eli was 2 years old, Monica and Kevin sent a letter and a photo of Eli to his biological mother, describing a bright, happy child. The next day, the Cambodian mother tearfully asked an adoption agency to send her baby daughter to join Eli and his American family. Although Grace's early environment was very depleted, her biological mother's loving care—holding gently, speaking softly, playfully stimulating, and breastfeeding—likely prevented irreversible damage to her brain.

In the Bucharest Early Intervention Project, 136 institutionalized Romanian babies were randomized into conditions of

either care as usual or transfer to high-quality foster families between 6 and 31 months of age. Specially trained social workers provided foster parents with counseling and support. Follow-ups between 2½ and 12 years revealed that the foster-care group exceeded the institutional-care group in intelligence test scores, language skills, emotional responsiveness, social skills, EEG and ERP assessments of brain development, and adaptive cortisol levels (Fox, Nelson, & Zeanah, 2013; Nelson, Fox, & Zeanah, 2014; McLaughlin et al., 2015). Consistent with an early sensitive period, on all measures, earlier foster placement predicted better outcomes.

In addition to impoverished environments, ones that overwhelm children with expectations beyond their current capacities interfere with the brain's potential. In recent years, expensive early learning centers as well as “educational” tablets and DVDs have become widespread. Within these contexts, infants are trained with letter and number flash cards, and toddlers are given a full curriculum of reading, math, science, art, and more. There is no evidence that these programs yield smarter “superbabies” (Principe, 2011). To the contrary, trying to prime infants with stimulation for which they are not ready can cause them to withdraw, thereby threatening their interest in learning and creating conditions much like stimulus deprivation!

How, then, can we characterize appropriate stimulation during the early years? To answer this question, researchers distinguish between two types of brain development. The first, **experience-expectant brain growth**, refers to the young brain's rapidly devel-

oping organization, which depends on ordinary experiences—opportunities to explore the environment, interact with people, and hear language and other sounds. As a result of millions of years of evolution, the brains of all infants, toddlers, and young children *expect* to encounter these experiences and, if they do, grow normally. The second type of brain development, **experience-dependent brain growth**, occurs throughout our lives. It consists of additional growth and refinement of established brain structures as a result of specific learning experiences that vary widely across individuals and cultures (Greenough & Black, 1992). Reading and writing, playing computer games, weaving an intricate rug, and practicing the violin are examples. The brain of a violinist differs in certain ways from the brain of a poet because each has exercised different brain regions for a long time.

Experience-expectant brain development occurs early and naturally, as caregivers offer babies and preschoolers age-appropriate play materials and engage them in enjoyable daily routines—a shared meal, a game of peekaboo, a bath before bed, a picture book to talk about, or a song to sing. The resulting growth provides the foundation for later-occurring, experience-dependent development (Belsky & de Haan, 2011; Huttenlocher, 2002). No evidence exists for a sensitive period in the first few years for mastering skills that depend on extensive training, such as reading, musical performance, or gymnastics. To the contrary, rushing early learning harms the brain by overwhelming its neural circuits, thereby reducing the brain's sensitivity to the everyday experiences it needs for a healthy start in life.

© AURELIE AND MORGAN DAVID DE LOSSY/CULTURA CREATIVE/ALAMY

© ROBERTO WESTBROOK/CORBIS

Experience-expectant brain growth depends on ordinary, stimulating experiences—like this toddler's exploration of a mossy log. It provides the foundation for experience-dependent brain growth—refinements due to culturally specific learning. But too much emphasis on training at an early age—for example, drill on mastering the ABCs—can interfere with access to everyday experiences the young brain needs to grow optimally.

## Changing States of Arousal

Rapid brain growth means that the organization of sleep and wakefulness changes substantially between birth and 2 years, and fussiness and crying also decline. The newborn baby takes round-the-clock naps that total about 16 to 18 hours. Total sleep time declines slowly; the average 2-year-old still needs 12 to 13 hours. But periods of sleep and wakefulness become fewer and longer, and the sleep–wake pattern increasingly conforms to a night–day schedule. Most 6- to 9-month-olds take two daytime naps; by about 18 months, children generally need only one nap (Galland et al., 2012). Between ages 3 and 5, napping subsides.

These changing arousal patterns are due to brain development, but they are also affected by cultural beliefs and practices and by parents' needs (Super & Harkness, 2002). Dutch parents, for example, view sleep regularity as far more important than U.S. parents do. And whereas U.S. parents regard a predictable sleep schedule as emerging naturally from within the child, Dutch parents believe that a schedule must be imposed, or the baby's development might suffer (Super & Harkness, 2010; Super et al., 1996). At age 6 months, Dutch babies are put to bed earlier and sleep, on average, 2 hours more per day than their U.S. agemates.

Motivated by demanding work schedules and other needs, many Western parents try to get their babies to sleep through the night as early as 3 to 4 months by offering an evening feeding. But infants who receive more milk or solid foods during the day are not less likely to wake, though they feed less at night (Brown & Harries, 2015). Trying to induce young infants to sleep through the night is at odds with their neurological capacities: Not until the middle of the first year is the secretion of *melatonin*, a hormone within the brain that promotes drowsiness, much greater at night than during the day (Sadeh, 1997).

Furthermore, as the Cultural Influences box on page 126 reveals, isolating infants to promote sleep is rare elsewhere in the world. When babies sleep close to their parents, their average sleep period remains constant at three hours from 1 to 8 months of age. Only at the end of the first year, as REM sleep (the state that usually prompts waking) declines, do infants move in the direction of an adultlike sleep–wake schedule (Ficca et al., 1999).

Even after babies sleep through the night, they continue to wake occasionally. In studies carried out in Australia, Israel, and the United States, night wakings increased around 6 months and again between 1½ and 2 years (Armstrong, Quinn, & Dadds, 1994; Scher, Epstein, & Tirosh, 2004; Scher et al., 1995). As Chapter 6 will reveal, around the middle of the first year, infants are forming a clear-cut attachment to their familiar caregiver and begin protesting when he or she leaves. And the challenges of toddlerhood—the ability to range farther from the caregiver and

**FIGURE 4.7** Relationship of bedtime routines to night-wakings in infancy/toddlerhood and the preschool years. In a large sample of mothers in 13 Western and Asian nations, the more consistently they reported using bedtime routines, the less often their infants, toddlers, and preschoolers woke during the night. Findings were similar for ease of falling asleep and amount of nighttime sleep. (From J. A. Mindell, A. M. Li, A. Sadeh, R. Kwon, & D. Y. T. Goh, 2015, “Bedtime Routines for Young Children: A Dose-Dependent Association with Sleep Outcomes,” *Sleep*, 38, p. 720. Copyright © 2015 by permission of the Associated Professional Sleep Societies, LLC. Reprinted by permission.)

increased awareness of the self as separate from others—often prompt anxiety, evident in disturbed sleep and clinginess. When parents offer comfort, these behaviors subside.

Finally, bedtime routines promote sleep as early as the first two years. In one study, over 10,000 mothers in 13 Western and Asian nations were asked to report on their bedtime practices and their newborn to 5-year-olds' sleep quality. Consistently engaging in bedtime routines—for example, rocking and singing in infancy, storybook reading in toddlerhood and early childhood—was associated with falling asleep more readily, waking less often, and getting more nighttime sleep throughout the entire age range (see Figure 4.7) (Mindell et al., 2015). Mothers who established regular bedtime routines in infancy and toddlerhood were more likely to maintain the practice in early childhood.

### Ask yourself

**CONNECT** Explain how either too little or too much stimulation can impair cognitive and emotional development in the early years.

**APPLY** Which infant enrichment program would you choose: one that emphasizes gentle talking and touching and social games, or one that includes reading and number drills and classical music lessons? Explain.

**REFLECT** What is your attitude toward parent–infant cosleeping? Is it influenced by your cultural background? Explain.

## Cultural Influences

### Cultural Variation in Infant Sleeping Arrangements

Western child-rearing advice from experts strongly encourages night-time separation of baby from parent. For example, the most recent edition of Benjamin Spock's *Baby and Child Care* recommends that babies sleep in their own room by 3 months of age, explaining, "By 6 months, a child who regularly sleeps in her parents' room may feel uneasy sleeping anywhere else" (Spock & Needlman, 2012, p. 62). And the American Academy of Pediatrics (2012b) has issued a controversial warning that parent–infant bedsharing increases the risk of sudden infant death syndrome (SIDS) and accidental suffocation.

Yet parent–infant cosleeping—in the same room and usually in the same bed—is the norm for approximately 90 percent of the world's population, in cultures as diverse as the Japanese, the rural Guatemalan Maya, the Inuit of northwestern Canada, and the !Kung of Botswana. Japanese and Korean children usually lie next to their mothers throughout infancy and early childhood, and many continue to sleep with a parent or other family member until adolescence (Yang & Hahn, 2002). Among the Maya, mother–infant bedsharing is interrupted only by the birth of a new baby, when the older child is moved next to the father or to another bed in the same room (Morelli et al., 1992). Bedsharing is also common in U.S. ethnic minority families (McKenna & Volpe, 2007). African-American children, for example, frequently fall asleep with their parents and remain with them for part or all of the night (Buswell & Spatz, 2007).

Cultural values strongly influence infant sleeping arrangements. In one study, researchers interviewed Guatemalan Mayan mothers and American middle-SES mothers about their sleeping practices. Mayan mothers stressed the importance of promoting an *interdependent self*, explaining that cosleeping builds a close parent–child bond, which is necessary for children to learn the ways of people around them. In contrast, American mothers emphasized an *independent self*, mentioning their desire to instill early

autonomy, prevent bad habits, and protect their own privacy (Morelli et al., 1992).

Over the past two decades, cosleeping has increased in Western nations. An estimated 11 percent of U.S. infants routinely bedshare, and an additional 30 to 35 percent sometimes do (Buswell & Spatz, 2007; Colson et al., 2013). Proponents of the practice say that it helps infants sleep, makes breastfeeding more convenient, and provides valuable bonding time (McKenna & Volpe, 2007).

During the night, babies who sleep with their parents breastfeed three times longer than infants who sleep alone. Because infants arouse to nurse more often when sleeping next to their mothers, some researchers believe that cosleeping may actually help safeguard babies at risk for SIDS (see page 106 in Chapter 3). Consistent with this view, SIDS is rare in Asian cultures where bedsharing is widespread, including Cambodia, China, Japan, Korea, Thailand, and Vietnam (McKenna, 2002; McKenna & McDade, 2005).

Critics warn that bedsharing will promote emotional problems, especially excessive dependency. Yet a longitudinal study following children from the end of pregnancy through age 18 showed that young people who had bedshared in the early years were no different from others in any aspect of adjustment (Okami, Weisner, & Olmstead, 2002). A more serious concern is that infants might become trapped under the parent's body or in soft bedding and suffocate. Parents who are obese or who use alcohol, tobacco, or mood-altering drugs do pose a serious risk to bedsharing babies, as does the use of quilts and comforters or an overly soft mattress (American Academy of Pediatrics, 2012b; Carpenter et al., 2013).

But with appropriate precautions, parents and infants can cosleep safely (Ball & Volpe, 2013). In cultures where cosleeping is widespread, parents and infants usually sleep with

ERIC LAFORGUE/GAMMA-RAPHO VIA GETTY IMAGES

This Vietnamese mother and child sleep together—a practice common in their culture and around the globe. Hard wooden sleeping surfaces protect cosleeping children from entrapment in soft bedding.

light covering on hard surfaces, such as firm mattresses, floor mats, and wooden planks, or infants sleep in a cradle or hammock next to the parents' bed (McKenna, 2002). And when sharing the same bed, infants typically lie on their back or side facing the mother—positions that promote frequent, easy communication between parent and baby and arousal if breathing is threatened.

Finally, breastfeeding mothers usually assume a distinctive sleeping posture: They face the infant, with knees drawn up under the baby's feet and arm above the baby's head. Besides facilitating feeding, the position prevents the infant from sliding down under covers or up under pillows (Ball, 2006). Because this posture is also seen in female great apes while sharing sleeping nests with their infants, researchers believe it may have evolved to enhance infant safety.

Some researchers point out that placing too much emphasis on separate sleeping may have risky consequences—for example, inducing tired parents to avoid feeding their babies in bed in favor of using dangerously soft sofas (Bartick & Smith, 2014). Pediatricians are wise to discuss the safety of each infant's sleep environment with parents, while taking into account cultural values and motivations (Ward, 2015). Then they can work within that framework to create a safe sleep environment.

## Influences on Early Physical Growth

**4.4** Cite evidence that heredity and nutrition both contribute to early physical growth.

Physical growth, like other aspects of development, results from a complex interplay between genetic and environmental factors. Heredity, nutrition, and emotional well-being all affect early physical growth.

### Heredity

Because identical twins are much more alike in body size than fraternal twins, we know that heredity is important in physical growth (Dubois et al., 2012). When diet and health are adequate, height and rate of physical growth are largely influenced by heredity. In fact, as long as negative environmental influences such as poor nutrition or illness are not severe, children and adolescents typically show *catch-up growth*—a return to a genetically influenced growth path once conditions improve. Still, the health of the brain, the heart, the digestive system, and many other internal organs may be permanently compromised. (Recall the consequences of inadequate prenatal nutrition for long-term health, discussed on page 88 in Chapter 3.)

Genetic makeup also affects body weight: The weights of adopted children correlate more strongly with those of their biological than of their adoptive parents (Kinnunen, Pietilainen, & Rissanen, 2006). At the same time, environment—in particular, nutrition—plays an especially important role.

### Nutrition

Nutrition is especially crucial for development in the first two years because the baby's brain and body are growing so rapidly. Pound for pound, an infant's energy needs are at least twice those of an adult. Twenty-five percent of infants' total caloric intake is devoted to growth, and babies need extra calories to keep rapidly developing organs functioning properly (Meyer, 2009).

**Breastfeeding versus Bottle-Feeding.** Babies need both enough food and the right kind of food. In early infancy, breastfeeding is ideally suited to their needs, and bottled formulas try to imitate it. Applying What We Know on page 128 summarizes major nutritional and health advantages of breastfeeding.

Because of these benefits, breastfed babies in poverty-stricken regions are much less likely to be malnourished and 6 to 14 times more likely to survive the first year of life. The World Health Organization recommends breastfeeding until age 2 years, with solid foods added at 6 months. These practices, if widely followed, would save the lives of more than 800,000 infants annually (World Health Organization, 2015f). Even breastfeeding for just a few weeks offers some protection against respiratory and intestinal infections, which are devastating to young

children in developing countries. Also, because a nursing mother is less likely to get pregnant, breastfeeding helps increase spacing between siblings, a major factor in reducing infant and childhood deaths in nations with widespread poverty. (Note, however, that breastfeeding is not a reliable method of birth control.)

Yet many mothers in the developing world do not know about these benefits. In Africa, the Middle East, and Latin America, most babies get some breastfeeding, but fewer than 40 percent are exclusively breastfed for the first six months, and one-third are fully weaned from the breast before 1 year (UNICEF, 2015). In place of breast milk, mothers give their babies commercial formula or low-grade nutrients, such as rice water or highly diluted cow or goat milk. Contamination of these foods as a result of poor sanitation is common and often leads to illness and infant death. The United Nations has encouraged all hospitals and maternity units in developing countries to promote breastfeeding as long as mothers do not have viral or bacterial infections (such as HIV or tuberculosis) that can be transmitted to the baby. Today, most developing countries have banned the practice of giving free or subsidized formula to new mothers.

Partly as a result of the natural childbirth movement, breastfeeding has become more common in industrialized nations, especially among well-educated women. Today, 79 percent of American mothers begin breastfeeding after birth, but about half stop by 6 months (Centers for Disease Control and Prevention, 2014a). Not surprisingly, mothers who return to work sooner wean their babies from the breast earlier (Smith & Forrester, 2013). But mothers who cannot be with their infants all the time can still combine breast- and bottle-feeding. The U.S. Department of Health and Human Services (2011) advises exclusive breastfeeding for the first 6 months and inclusion of breast milk in the baby's diet until at least 1 year.

© LIBA TAYLOR/ALAMY

Midwives in India support a mother as she learns to breastfeed her infant. Breastfeeding is especially important in developing countries, where it helps protect babies against life-threatening infections and early death.

## Applying what we Know

### Reasons to Breastfeed

NUTRITIONAL AND HEALTH ADVANTAGES	EXPLANATION
Provides the correct balance of fat and protein	Compared with the milk of other mammals, human milk is higher in fat and lower in protein. This balance, as well as the unique proteins and fats contained in human milk, is ideal for a rapidly myelinating nervous system.
Ensures nutritional completeness	A mother who breastfeeds need not add other foods to her infant's diet until the baby is 6 months old. The milks of all mammals are low in iron, but the iron contained in breast milk is much more easily absorbed by the baby's system. Consequently, bottle-fed infants need iron-fortified formula.
Helps ensure healthy physical growth	One-year-old breastfed babies are leaner (have a higher percentage of muscle to fat), a growth pattern that persists through the preschool years and that is associated with a reduction in later overweight and obesity.
Protects against many diseases	Breastfeeding transfers antibodies and other infection-fighting agents from mother to baby and enhances functioning of the immune system. Compared with bottle-fed infants, breastfed babies have far fewer allergic reactions and respiratory and intestinal illnesses. Breast milk also has anti-inflammatory effects, which reduce the severity of illness symptoms. Breastfeeding in the first four months (especially when exclusive) is linked to lower blood cholesterol levels in adulthood and, thereby, may help prevent cardiovascular disease.
Protects against faulty jaw development and tooth decay	Sucking the mother's nipple instead of an artificial nipple helps avoid malocclusion, a condition in which the upper and lower jaws do not meet properly. It also protects against tooth decay due to sweet liquid remaining in the mouths of infants who fall asleep while sucking on a bottle.
Ensures digestibility	Because breastfed babies have a different kind of bacteria growing in their intestines than do bottle-fed infants, they rarely suffer from constipation or other gastrointestinal problems.
Smooths the transition to solid foods	Breastfed infants accept new solid foods more easily than do bottle-fed infants, perhaps because of their greater experience with a variety of flavors, which pass from the maternal diet into the mother's milk.

Sources: American Academy of Pediatrics, 2012a; Druet et al., 2012; Ip et al., 2009; Owen et al., 2008.

Women who do not breastfeed sometimes worry that they are depriving their baby of an experience essential for healthy psychological development. Yet breastfed and bottle-fed infants in industrialized nations do not differ in quality of the mother–infant relationship or in later emotional adjustment (Jansen, de Weerth, & Riksen-Walraven, 2008; Lind et al., 2014). Some studies report a slight advantage in intelligence for children and adolescents who were breastfed, after controlling for maternal intelligence, SES, and other factors (Belfort et al., 2013; Kanazawa, 2015). Other studies, however, find no cognitive benefits (Walfisch et al., 2013).

**Are Chubby Babies at Risk for Later Overweight and Obesity?** From early infancy, Timmy was an enthusiastic eater who nursed vigorously and gained weight quickly. By 5 months, he began reaching for food on his mother's plate. Vanessa wondered: Was she overfeeding Timmy and increasing his chances of becoming overweight?

Most chubby babies thin out during toddlerhood and early childhood, as weight gain slows and they become more active. Infants and toddlers can eat nutritious foods freely without risk of becoming overweight. But recent evidence does indicate a

strengthening relationship between rapid weight gain in infancy and later obesity (Druet et al., 2012). The trend may be due to the rise in overweight and obesity among adults, who promote unhealthy eating habits in their young children. Interviews with 1,500 U.S. parents of 4- to 24-month-olds revealed that many routinely served older infants and toddlers french fries, pizza, candy, sugary fruit drinks, and soda. On average, infants consumed 20 percent and toddlers 30 percent more calories than they needed (Siega-Riz et al., 2010). At the same time, as many as one-fourth ate no fruits and one-third no vegetables.

How can parents prevent their infants from becoming overweight children and adults? One way is to breastfeed exclusively for the first six months, which is associated with slower weight gain over the first year, leaner body build through early childhood, and 10 to 20 percent reduced obesity risk in later life (Gunnarsdottir et al., 2010; Koletzko et al., 2013). Another strategy is to avoid giving babies foods loaded with sugar, salt, and saturated fats. Once toddlers learn to walk, climb, and run, parents can also provide plenty of opportunities for energetic play. Finally, because research shows a correlation between excessive television viewing and overweight in older children, parents should limit the time very young children spend in front of the TV.

## Malnutrition

Osita is an Ethiopian 2-year-old whose mother has never had to worry about his gaining too much weight. When she weaned him at 1 year, he had little to eat besides starchy rice flour cakes. Soon his belly enlarged, his feet swelled, his hair fell out, and a rash appeared on his skin. His bright-eyed curiosity vanished, and he became irritable and listless.

In developing countries and war-torn areas where food resources are limited, malnutrition is widespread. Malnutrition contributes to one-third of worldwide infant and early childhood deaths—about 2.1 million children annually. It is also responsible for growth stunting of nearly one-third of the world's children under age 5 (World Health Organization, 2015c). The 8 percent who are severely affected suffer from two dietary diseases.

**Marasmus** is a wasted condition of the body caused by a diet low in all essential nutrients. It usually appears in the first year of life when a baby's mother is too malnourished to produce enough breast milk and bottle-feeding is also inadequate. Her starving baby becomes painfully thin and is in danger of dying.

Osita has **kwashiorkor**, caused by an unbalanced diet very low in protein. The disease usually strikes after weaning, between 1 and 3 years of age. It is common in regions where children get just enough calories from starchy foods but little protein. The child's body responds by breaking down its own protein reserves, which causes the swelling and other symptoms that Osita experienced.

Children who survive these extreme forms of malnutrition often suffer from lasting damage to the brain, heart, liver, pancreas, and other organs (Müller & Krawinkel, 2005; Spoelstra et al., 2012). When their diets do improve, they tend to gain

excessive weight (Black et al., 2013). A malnourished body protects itself by establishing a low basal metabolism rate, which may endure after nutrition improves. Also, malnutrition may disrupt appetite control centers in the brain, causing the child to overeat when food becomes plentiful.

Learning and behavior are also seriously affected. Animal evidence reveals that a deficient diet permanently reduces brain weight and alters the production of neurotransmitters in the brain—an effect that can disrupt all aspects of development (Haller, 2005). Children who experienced marasmus or kwashiorkor show poor fine-motor coordination, have difficulty paying attention, often display conduct problems, and score low on intelligence tests into adulthood (Galler et al., 1990, 2012; Waber et al., 2014). They also display a more intense stress response to fear-arousing situations, perhaps caused by the constant, gnawing pain of hunger (Fernald & Grantham-McGregor, 1998).

Recall from our discussion of prenatal malnutrition in Chapter 3 that irritability and passivity of malnourished children compound the developmental consequences of poor diet. These behaviors may appear even when nutritional deprivation is only mild to moderate. Because government-supported supplementary food programs do not reach all families in need, an estimated 19 percent of U.S. children suffer from *food insecurity*—uncertain access to enough food for a healthy, active life. Food insecurity is especially high among single-parent families (35 percent) and low-income ethnic minority families—for example, African Americans and Hispanics (26 and 22 percent, respectively) (U.S. Department of Agriculture, 2015a). Although few of these children have marasmus or kwashiorkor, their physical growth and ability to learn are still affected.

*Left photo:* This baby of Niger, Africa, has marasmus, a wasted condition caused by a diet low in all essential nutrients. *Right photo:* The swollen abdomen of this toddler, also of Niger, is a symptom of kwashiorkor, which results from a diet very low in protein. If these children survive, they are likely to be growth stunted and to suffer from lasting organ damage and serious cognitive and emotional impairments.

## Ask yourself

**CONNECT** How are bidirectional influences between parent and child involved in the impact of malnutrition on psychological development?

**APPLY** Eight-month-old Shaun is well below average in height and painfully thin. What serious growth disorder does he likely have, and what type of intervention, in addition to dietary enrichment, will help restore his development?

**REFLECT** Imagine that you are the parent of a newborn baby. Describe feeding practices you would use, and ones you would avoid, to prevent overweight and obesity.

## Learning Capacities

**4.5** Describe infant learning capacities, the conditions under which they occur, and the unique value of each.

*Learning* refers to changes in behavior as the result of experience. Babies come into the world with fundamental learning capacities that permit them to profit from experience immediately. Infants are capable of two basic forms of learning, which were introduced in Chapter 1: classical and operant condition-

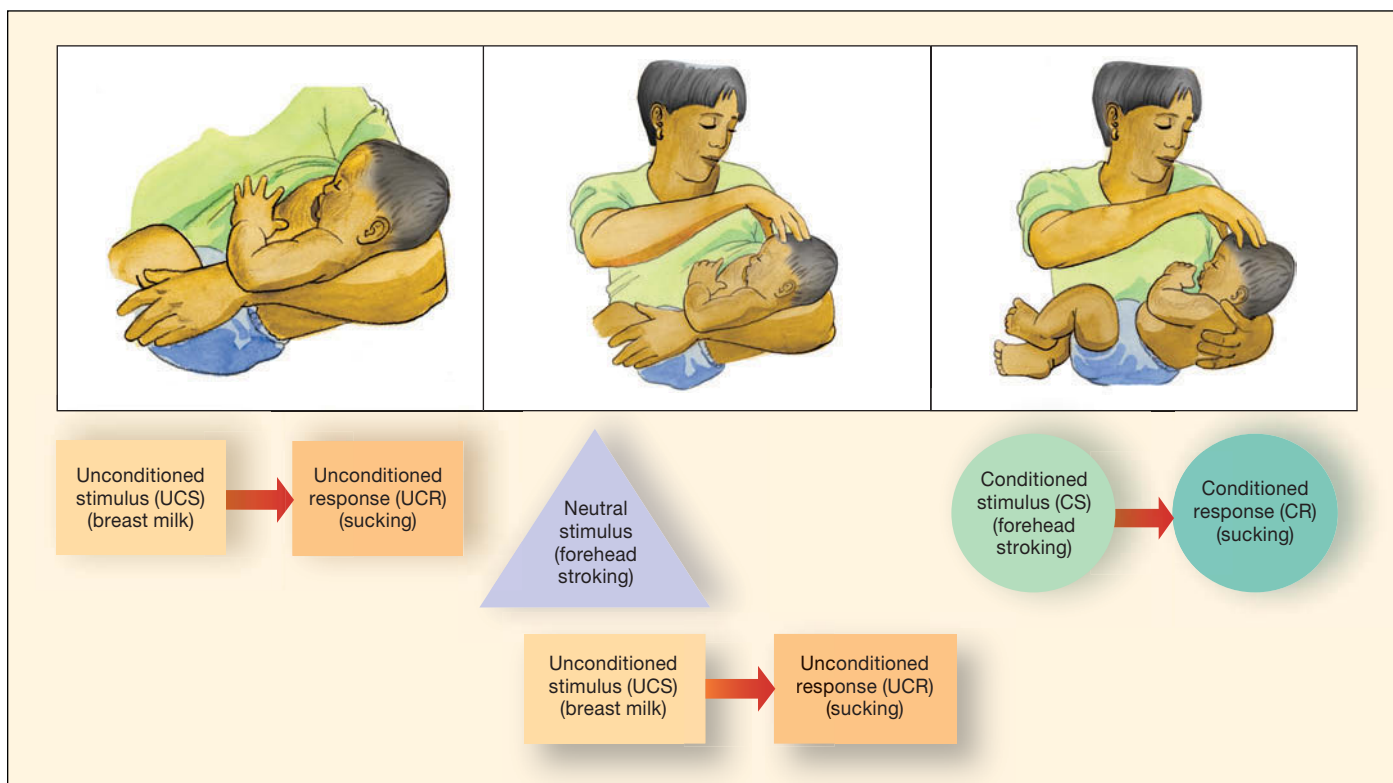

ing. They also learn through their natural preference for novel stimulation. Finally, shortly after birth, babies learn by observing others; they can imitate the facial expressions and gestures of adults.

## Classical Conditioning

Newborn reflexes, discussed in Chapter 3, make **classical conditioning** possible in the young infant. In this form of learning, a neutral stimulus is paired with a stimulus that leads to a reflexive response. Once the baby's nervous system makes the connection between the two stimuli, the neutral stimulus produces the behavior by itself. Classical conditioning helps infants recognize which events usually occur together in the everyday world, so they can anticipate what is about to happen next. As a result, the environment becomes more orderly and predictable. Let's take a closer look at the steps of classical conditioning.

As Carolyn settled down in the rocking chair to nurse Caitlin, she often stroked Caitlin's forehead. Soon Carolyn noticed that each time she did this, Caitlin made sucking movements. Caitlin had been classically conditioned. Figure 4.8 shows how it happened:

1. Before learning takes place, an **unconditioned stimulus (UCS)** must consistently produce a reflexive, or **unconditioned, response (UCR)**. In Caitlin's case, sweet breast milk (UCS) resulted in sucking (UCR).

**FIGURE 4.8** The steps of classical conditioning. This example shows how a mother classically conditioned her baby to make sucking movements by stroking the baby's forehead at the beginning of feedings.

2. To produce learning, a *neutral stimulus* that does not lead to the reflex is presented just before, or at about the same time as, the UCS. Carolyn stroked Caitlin's forehead as each nursing period began. The stroking (neutral stimulus) was paired with the taste of milk (UCS).
3. If learning has occurred, the neutral stimulus by itself produces a response similar to the reflexive response. The neutral stimulus is then called a **conditioned stimulus (CS)**, and the response it elicits is called a **conditioned response (CR)**. We know that Caitlin has been classically conditioned because stroking her forehead outside the feeding situation (CS) results in sucking (CR).

If the CS is presented alone enough times, without being paired with the UCS, the CR will no longer occur, an outcome called *extinction*. In other words, if Carolyn repeatedly strokes Caitlin's forehead without feeding her, Caitlin will gradually stop sucking in response to stroking.

Young infants can be classically conditioned most easily when the association between two stimuli has survival value. In the example just described, learning which stimuli regularly accompany feeding improves the infant's ability to get food and survive (Blass, Ganchrow, & Steiner, 1984).

In contrast, some responses, such as fear, are very difficult to classically condition in young babies. Until infants have the motor skills to escape unpleasant events, they have no biological need to form these associations. After age 6 months, however, fear is easy to condition. In Chapter 6, we will discuss the development of fear and other emotional reactions.

## Operant Conditioning

In classical conditioning, babies build expectations about stimulus events in the environment, but they do not influence the stimuli that occur. In **operant conditioning**, infants act, or *operate*, on the environment, and stimuli that follow their behavior change the probability that the behavior will occur again. A stimulus that increases the occurrence of a response is called a **reinforcer**. For example, sweet liquid *reinforces* the sucking response in newborns. Removing a desirable stimulus or presenting an unpleasant one to decrease the occurrence of a response is called **punishment**. A sour-tasting fluid *punishes* newborns' sucking response, causing them to purse their lips and stop sucking entirely.

Many stimuli besides food can serve as reinforcers of infant behavior. For example, newborns will suck faster on a nipple when their rate of sucking produces interesting sights and sounds, including visual designs, music, or human voices (Floccia, Christophe, & Bertoncini, 1997). As these findings suggest, operant conditioning is a powerful tool for finding out what stimuli babies can perceive and which ones they prefer.

As infants get older, operant conditioning includes a wider range of responses and stimuli. For example, researchers have hung mobiles over the cribs of 2- to 6-month-olds. When the

baby's foot is attached to the mobile with a long cord, the infant can, by kicking, make the mobile turn. Under these conditions, it takes only a few minutes for infants to start kicking vigorously (Rovee-Collier, 1999; Rovee-Collier & Barr, 2001). As you will see in Chapter 5, operant conditioning with mobiles is frequently used to study infants' memory and their ability to group similar stimuli into categories. Once babies learn the kicking response, researchers see how long and under what conditions they retain it when exposed again to the original mobile or to mobiles with varying features.

Operant conditioning also plays a vital role in the formation of social relationships. As the baby gazes into the adult's eyes, the adult looks and smiles back, and then the infant looks and smiles again. As the behavior of each partner reinforces the other, both continue their pleasurable interaction. In Chapter 6, we will see that this contingent responsiveness contributes to the development of infant-caregiver attachment.

## Habituation

At birth, the human brain is set up to be attracted to novelty. Infants tend to respond more strongly to a new element that has entered their environment, an inclination that ensures that they will continually add to their knowledge base. **Habituation** refers to a gradual reduction in the strength of a response due to repetitive stimulation. Time spent looking at the stimulus, heart rate, respiration rate, and brain activity may all decline, indicating a loss of interest. Once this has occurred, a new stimulus—a change in the environment—causes responsiveness to return to a high level, an increase called **recovery**. For example, when you walk through a familiar space, you notice things that are new and different—a recently hung picture on the wall or a piece of furniture that has been moved. Habituation and recovery make learning more efficient by focusing our attention on those aspects of the environment we know least about.

Researchers investigating infants' understanding of the world rely on habituation and recovery more than any other learning capacity. For example, a baby who first *habituates* to a visual pattern (a photo of a baby) and then *recovers* to a new one (a photo of a bald man) appears to remember the first stimulus and perceive the second one as new and different from it. This method of studying infant perception and cognition, illustrated in Figure 4.9 on page 132, can be used with newborns, including preterm infants (Kavšek & Bornstein, 2010). It has even been used to study the fetus's sensitivity to external stimuli in the third trimester of pregnancy—for example, by measuring changes in fetal heart rate or brain waves when various repeated sounds are presented, followed by a different sound (see page 81 in Chapter 3).

Recovery to a new stimulus, or *novelty preference*, assesses infants' *recent memory*. Think about what happens when you return to a place you have not seen for a long time. Instead of attending to novelty, you are likely to focus on aspects that are familiar: "I recognize that—I've been here before!" Like adults, infants shift from a novelty preference to a *familiarity preference*

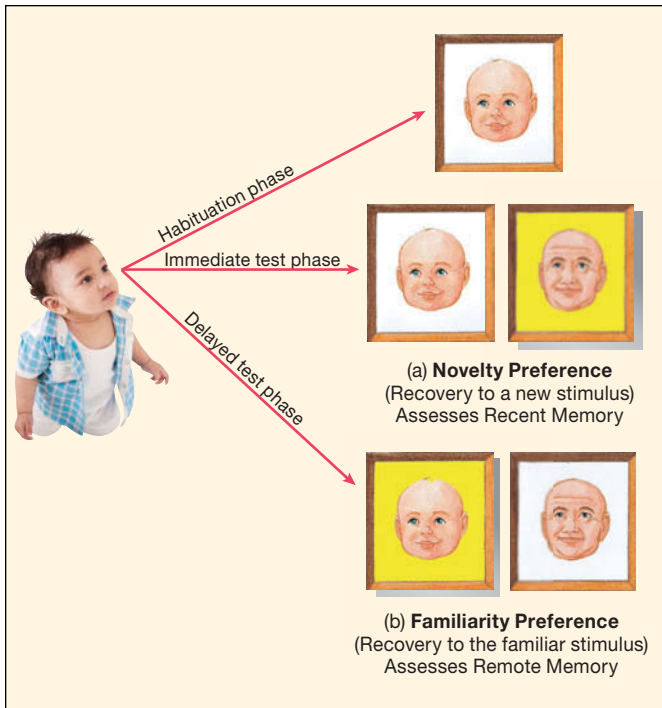

PHOTO © PRASHANT ZIFOTOLIA

**FIGURE 4.9** Using habituation to study infant perception and cognition. In the habituation phase, infants view a photo of a baby until their looking declines. In the test phase, infants are again shown the baby photo, but this time it appears alongside a photo of a bald-headed man. (a) When the test phase occurs soon after the habituation phase (within minutes, hours, or days, depending on the age of the infants), participants who remember the baby face and distinguish it from the man's face show a *novelty preference*; they recover to (spend more time looking at) the new stimulus. (b) When the test phase is delayed for weeks or months, infants who continue to remember the baby face shift to a *familiarity preference*; they recover to the familiar baby face rather than to the novel man's face.

as more time intervenes between habituation and test phases in research. That is, babies recover to the familiar stimulus rather than to a novel stimulus (see Figure 4.9) (Colombo, Brez, & Curtindale, 2013; Flom & Bahrick, 2010; Richmond, Colombo, & Hayne, 2007). By focusing on that shift, researchers can also use habituation to assess *remote memory*, or memory for stimuli to which infants were exposed weeks or months earlier.

As Chapter 5 will reveal, habituation research has greatly enriched our understanding of how long babies remember a wide range of stimuli. And by varying stimulus features, researchers can use habituation and recovery to study babies' ability to categorize stimuli as well.

## Imitation

Babies come into the world with a primitive ability to learn through **imitation**—by copying the behavior of another person. For example, Figure 4.10 shows a human newborn imitating two adult facial expressions (Meltzoff & Moore, 1977). The newborn's capacity to imitate extends to certain gestures, such as

head and index-finger movements, and has been demonstrated in many ethnic groups and cultures (Meltzoff & Kuhl, 1994; Nagy et al., 2005). As the figure reveals, even newborn primates, including chimpanzees (our closest evolutionary relatives), imitate some behaviors (Ferrari et al., 2006; Myowa-Yamakoshi et al., 2004).

Nevertheless, some studies have failed to reproduce the human findings (see, for example, Anisfeld, 2005). And because newborn mouth and tongue movements occur with increased frequency to almost any arousing change in stimulation (such as lively music or flashing lights), some researchers argue that certain newborn “imitative” responses are actually mouthing—a common early exploratory response to interesting stimuli (Jones, 2009). Furthermore, imitation is harder to induce in babies 2 to 3 months old than just after birth. Therefore, skeptics believe that the newborn imitative capacity is little more than an automatic response that declines with age, much like a reflex (Heyes, 2005).

Others claim that newborns imitate a variety of facial expressions and head movements with effort and determination, even after short delays—when the adult is no longer demonstrating the behavior (Meltzoff & Williamson, 2013; Paukner, Ferrari, & Suomi, 2011). Furthermore, these investigators argue that imitation—unlike reflexes—does not decline. Human babies several months old often do not imitate an adult's behavior right away because they first try to play familiar social games—mutual gazing, cooing, smiling, and waving their arms. But when an adult models a gesture repeatedly, older human infants soon get down to business and imitate (Meltzoff & Moore, 1994). Similarly, imitation declines in baby chimps around 9 weeks of age, when mother–baby mutual gazing and other face-to-face exchanges increase.

According to Andrew Meltzoff, newborns imitate much as older children and adults do—by actively trying to match body movements they *see* with ones they *feel* themselves make. With successive tries, they imitate a modeled gesture with greater accuracy (Meltzoff & Williamson, 2013). Later we will encounter evidence that young babies are remarkably adept at coordinating information across sensory systems.

Scientists have identified specialized cells in motor areas of the cerebral cortex in primates—called **mirror neurons**—that may underlie early imitative capacities. Mirror neurons fire identically when a primate hears or sees an action and when it carries out that action on its own (Ferrari & Coudé, 2011). Brain-imaging research reveals functioning neural-mirroring systems in human infants by the middle of the first year that enable them to observe another's behavior (such as tapping a rattle or ringing a bell) while simulating the behavior in their own brain (Shimada & Hiraki, 2006). These systems are believed to be the biological basis of a variety of interrelated, complex social abilities in addition to imitation, including empathic sharing of emotions and understanding others' intentions.

Still, Meltzoff's view of newborn imitation as a flexible, voluntary capacity remains controversial. Some critics contend

**FIGURE 4.10 Imitation by human and chimpanzee newborns.** The human infants in the middle row imitating (left) tongue protrusion and (right) mouth opening are 2 to 3 weeks old. The chimpanzee imitating both facial expressions is 2 weeks old. (From A. N. Meltzoff & M. K. Moore, 1977, "Imitation of Facial and Manual Gestures by Human Neonates," *Science*, 198, p. 75. Copyright © 1977 by AAAS. Reprinted with permission of the American Association for the Advancement of Science conveyed through Copyright Clearance Center, Inc., and Dr. Andrew Meltzoff. And from M. Myowa-Yamakoshi et al., 2004, "Imitation in Neonatal Chimpanzees [*Pan Troglodytes*]." *Developmental Science*, 7, p. 440. Copyright © 2004 by John Wiley & Sons. that babies learn to imitate gradually through rich social experiences (Ray & Heyes, 2011). And even researchers who believe that newborns can imitate agree that many opportunities to see oneself act, to watch others' responses, and to engage in imitative games with caregivers are required for infants to become proficient imitators (Marshall & Meltzoff, 2011). Consistent with this view, human neural-mirroring systems, though possibly functional at birth, undergo an extended period of develop-

ment (Ferrari et al., 2013; Heyes, 2010). And as we will see in Chapter 5, the capacity to imitate expands greatly over the first two years.

However limited it is at birth, imitation is a powerful means of learning. Using imitation, infants explore their social world, learning from other people. As they notice similarities between their own actions and those of others, they experience other people as "like me" and learn about themselves (Meltzoff & Williamson, 2013). By tapping into infants' ability to imitate, adults can get infants to exhibit desirable behaviors. Finally, caregivers take great pleasure in a baby who participates in imitative exchanges—a capacity that strengthens the parent–infant bond.

## Ask yourself

**CONNECT** Which learning capacities contribute to an infant's first social relationships? Explain, providing examples.

**APPLY** Nine-month-old Byron has a toy with large, colored push buttons on it. Each time he pushes a button, he hears a nursery tune. Which learning capacity is the manufacturer of this toy taking advantage of? What can Byron's play with the toy reveal about his perception of sound patterns?

## Motor Development

**4.6** Describe dynamic systems theory of motor development, along with factors that influence motor progress in the first two years.

Carolyn, Monica, and Vanessa each kept a baby book, filled with proud notations about when their children first held up their heads, reached for objects, sat by themselves, and walked alone. Parents are understandably excited about these new motor skills, which allow babies to master their bodies and the environment in new ways. For example, sitting upright gives infants a new perspective on the world. Reaching permits babies to find out about objects by acting on them. And when infants can move on their own, their opportunities for exploration multiply.

Babies' motor achievements have a powerful effect on their social relationships. When Caitlin crawled at 7½ months, Carolyn and David began to restrict her movements by saying no and expressing mild impatience. When she walked three days after her first birthday, the first "testing of wills" occurred (Biringen et al., 1995). Despite her mother's warnings, she sometimes pulled items from shelves that were off limits. "I said, 'Don't do that!'" Carolyn would say firmly, taking Caitlin's hand and redirecting her attention.

At the same time, newly walking babies more actively attend to and initiate social interaction (Clearfield, 2011; Karasik et al., 2011). Caitlin frequently toddled over to her parents to express a greeting, give a hug, or show them objects of interest. Carolyn

and David, in turn, increased their verbal responsiveness, expressions of affection, and playful activities. And when Caitlin encountered risky situations, such as a sloping walkway or a dangerous object, Carolyn and David intervened, combining emotional warnings with rich verbal and gestural information that helped Caitlin notice critical features of her surroundings, regulate her motor actions, and acquire language (Karasik et al., 2008). Caitlin's delight as she worked on new motor skills triggered pleasurable reactions in others, which encouraged her efforts further. Motor, social, cognitive, and language competencies developed together and supported one another.

## The Sequence of Motor Development

*Gross-motor development* refers to control over actions that help infants get around in the environment, such as crawling, standing, and walking. *Fine-motor development* has to do with smaller movements, such as reaching and grasping. Table 4.2 shows the average age at which U.S. infants and toddlers achieve a variety

of gross- and fine-motor skills. It also presents the age range during which most babies accomplish each skill, indicating large individual differences in *rate* of motor progress. Also, a baby who is a late reacher will not necessarily be a late crawler or walker. We would be concerned about a child's development only if many motor skills were seriously delayed.

Historically, researchers assumed that motor skills were separate, innate abilities that emerged in a fixed sequence governed by a built-in maturational timetable. This view has long been discredited. Rather, motor skills are interrelated. Each is a product of earlier motor attainments and a contributor to new ones. And children acquire motor skills in highly individual ways. For example, before her adoption, Grace spent most of her days lying in a hammock. Because she was rarely placed on her tummy and on firm surfaces that enabled her to move on her own, she did not try to crawl. As a result, she pulled to a stand and walked before she crawled! Babies display such skills as rolling, sitting, crawling, and walking in diverse orders rather than in the sequence implied by motor norms (Adolph & Robinson, 2013).

**TABLE 4.2**  
Gross- and Fine-Motor Development in the First Two Years

MOTOR SKILL	AVERAGE AGE ACHIEVED	AGE RANGE IN WHICH 90 PERCENT OF INFANTS ACHIEVE THE SKILL
When held upright, holds head erect and steady	6 weeks	3 weeks–4 months
When prone, lifts self by arms	2 months	3 weeks–4 months
Rolls from side to back	2 months	3 weeks–5 months
Grasps cube	3 months, 3 weeks	2–7 months
Rolls from back to side	4½ months	2–7 months
Sits alone	7 months	5–9 months
Crawls	7 months	5–11 months
Pulls to stand	8 months	5–12 months
Plays pat-a-cake	9 months, 3 weeks	7–15 months
Stands alone	11 months	9–16 months
Walks alone	11 months, 3 weeks	9–17 months
Builds tower of two cubes	11 months, 3 weeks	10–19 months
Scribbles vigorously	14 months	10–21 months
Walks up stairs with help	16 months	12–23 months
Jumps in place	23 months, 2 weeks	17–30 months
Walks on tiptoe	25 months	16–30 months

*Note:* These milestones represent overall age trends. Individual differences exist in the precise age at which each milestone is attained.

## Motor Skills as Dynamic Systems

According to **dynamic systems theory of motor development**, mastery of motor skills involves acquiring increasingly complex *systems of action*. When motor skills work as a system, separate abilities blend together, each cooperating with others to produce more effective ways of exploring and controlling the environment. For example, control of the head and upper chest combine into sitting with support. Kicking, rocking on all fours, and reaching combine to become crawling. Then crawling, standing, and stepping are united into walking (Adolph & Robinson, 2015; Thelen & Smith, 1998).

Each new skill is a joint product of four factors: (1) central nervous system development, (2) the body's movement capacities, (3) the goals the child has in mind, and (4) environmental supports for the skill. Change in any element makes the system less stable, and the child starts to explore and select new, more effective motor patterns.

The broader physical environment also profoundly influences motor skills. Infants with stairs in their home learn to crawl up stairs at an earlier age and also more readily master a back-descent strategy—the safest but also the most challenging position because the baby must turn around at the top, give up visual guidance of her goal, and crawl backward (Berger, Theuring, & Adolph, 2007). And if children were reared on the moon, with its reduced gravity, they would prefer jumping to walking or running!

### LOOK and LISTEN

Observe a newly crawling or walking baby. Note the goals that motivate the baby to move, along with the baby's effort and motor experimentation. Describe parenting behaviors and features of the environment that promote mastery of the skill.

When a skill is first acquired, infants must refine it. For example, in trying to crawl, Caitlin often collapsed on her tummy and moved backward. Soon she figured out how to propel herself forward by alternately pulling with her arms and pushing with her feet, “belly-crawling” in various ways for several weeks. As babies attempt a new skill, related, previously mastered skills often become less secure. As the novice walker experiments with balancing the body vertically over two small moving feet, balance during sitting may become temporarily less stable (Chen et al., 2007).

Motor mastery involves intense practice. In learning to walk, toddlers practice six or more hours a day, traveling the length of 29 football fields! They fall, on average, 17 times per hour but rarely cry, returning to motion within a few seconds (Adolph et al., 2012). Gradually their small, unsteady steps change to a longer stride, their feet move closer together, their toes point to the front, and their legs become symmetrically coordinated. As movements are repeated thousands of times, they promote new synaptic connections in the brain that govern motor patterns.

Dynamic systems theory shows us why motor development cannot be genetically determined. Because it is motivated by exploration and the desire to master new tasks and varies with context, heredity can map it out only at a general level. Rather than being *hardwired* into the nervous system, motor behaviors are *softly assembled* from multiple components, allowing for different paths to the same motor skill (Adolph & Robinson, 2015; Spencer, Perone, & Buss, 2011).

**Dynamic Motor Systems in Action.** To find out how infants acquire motor capacities, some studies have tracked babies from their first attempts at a skill until it became smooth and effortless. In one investigation, researchers held sounding toys alternately in front of infants' hands and feet, from the time they showed interest until they engaged in well-coordinated reaching and grasping (Galloway & Thelen, 2004). As Figure 4.11 illustrates, the infants violated the normative sequence of arm and hand control preceding leg and foot control, shown in Table 4.2. They first reached for the toys with their feet—as early as 8 weeks of age, at least a month before reaching with their hands!

Why did babies reach “feet first”? Because the hip joint constrains the legs to move less freely than the shoulder constrains the arms, infants could more easily control their leg movements. Consequently, foot reaching required far less practice than hand reaching. As these findings confirm, rather than following a strict sequence, the order in which motor skills develop depends on the anatomy of the body part being used, the surrounding environment, and the baby's efforts.

Furthermore, in building a more effective dynamic system, babies often use advances in one motor skill to support advances

**FIGURE 4.11** Reaching “feet first.” When sounding toys were held in front of babies' hands and feet, they reached with their feet as early as 8 weeks of age, a month or more before they reached with their hands. This 2½-month-old skillfully explores an object with her foot.

in others. For example, beginning to walk frees the hands for carrying, and new walkers like to fetch distant objects and transport them (Karasik, Tamis-LeMonda, & Adolph, 2011). Observations of new walkers reveal that, surprisingly, they fall less often when carrying objects than when their hands are empty (Karasik et al., 2012). Toddlers integrate their object carrying into their emerging “walking system,” using it to improve their balance.

**Cultural Variations in Motor Development.** Cross-cultural research further illustrates how early movement opportunities and a stimulating environment contribute to motor development. More than half a century ago, Wayne Dennis (1960) observed infants in Iranian orphanages who were deprived of the tantalizing surroundings that induce infants to acquire motor skills. These babies spent their days lying on their backs in cribs, without toys to play with. As a result, most did not move on their own until after 2 years of age. When they finally did move, the constant experience of lying on their backs led them to scoot in a sitting position rather than crawl on their hands and knees. Because babies who scoot come up against furniture with their feet, not their hands, they are far less likely to pull themselves to a standing position in preparation for walking. Indeed, by 3 to 4 years of age, only 15 percent of the Iranian orphans were walking alone.

Cultural variations in infant-rearing practices affect motor development. To ensure safety and ease toileting while parents work in the fields, mothers in rural northeastern China place infants on their backs in bags of sand (similar to kitty litter) for most of the day, continuing this practice into the second year. Compared with diapered infants in the same region, sandbag-reared babies are greatly delayed in sitting and walking (Mei, 1994). Among the Zinacanteco Indians of southern Mexico and the Gusii of Kenya, adults view babies who walk before they

know enough to keep away from cooking fires and weaving looms as dangerous to themselves and disruptive to others (Greenfield, 1992). Zinacanteco and Gusii parents actively discourage infants’ gross-motor progress.

In contrast, among the Kipsigis of Kenya and the West Indians of Jamaica, babies hold their heads up, sit alone, and walk considerably earlier than North American infants. In both societies, parents emphasize early motor maturity, practicing formal exercises to stimulate particular skills (Adolph, Karasik, & Tamis-LeMonda, 2010). In the first few months, babies are seated in holes dug in the ground, with rolled blankets to keep them upright. Walking is promoted by frequently standing babies in adults’ laps, bouncing them on their feet, and exercising the stepping reflex (Hopkins & Westra, 1988; Super, 1981). As parents in these cultures support babies in upright postures and rarely put them down on the floor, their infants usually skip crawling—a motor skill regarded as crucial in Western nations!

Finally, because it decreases exposure to “tummy time,” the current Western practice of having babies sleep on their backs to protect them from SIDS (see page 106 in Chapter 3) delays gross-motor milestones of rolling, sitting, and crawling (Scrutton, 2005). Regularly exposing infants to the tummy-lying position during waking hours prevents these delays.

## Fine-Motor Development: Reaching and Grasping

Of all motor skills, reaching may play the greatest role in infant cognitive development. By grasping things, turning them over, and seeing what happens when they are released, infants learn a great deal about the sights, sounds, and feel of objects. Because certain gross-motor attainments vastly change infants’ view of their surroundings, they promote manual coordination. When babies sit, and even more so when they stand and walk, they see the panorama of an entire room (Kretch, Franchak, & Adolph, 2014). In these positions, they focus mainly on the sights and sounds of nearby objects and want to explore them.

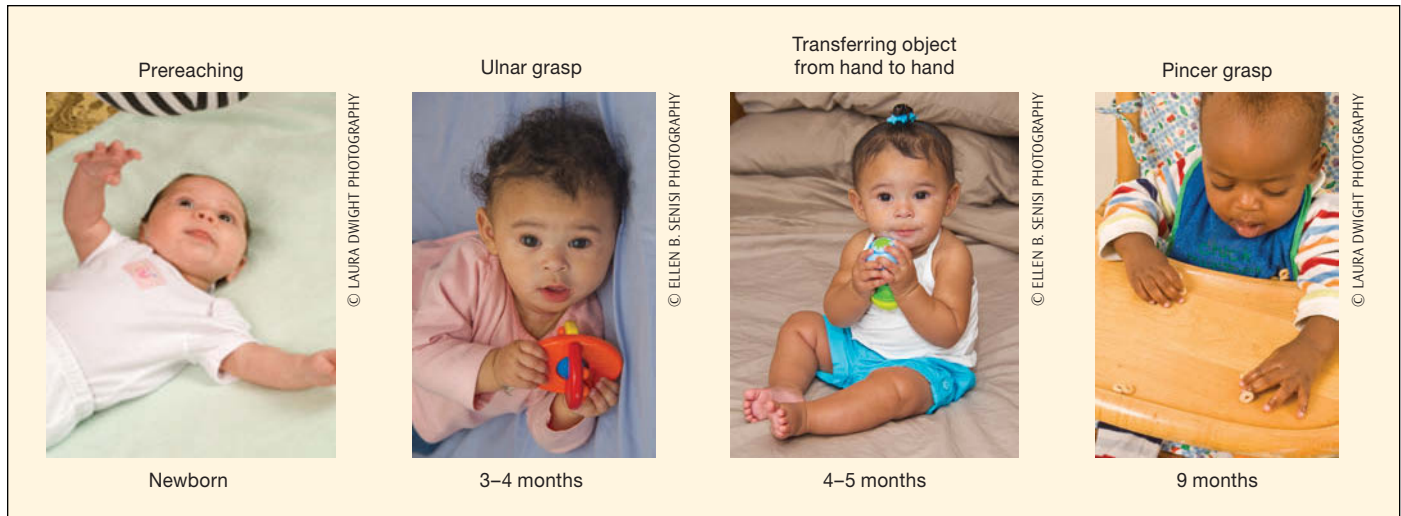

Reaching and grasping, like many other motor skills, start out as gross, diffuse activity and move toward mastery of fine movements. Figure 4.12 illustrates some milestones of reaching over the first nine months. Newborns make poorly coordinated swipes, called *prereaching*, toward an object in front of them, but because of poor arm and hand control they rarely contact the object. Like newborn reflexes, *prereaching* drops out around 7 weeks of age (von Hofsten, 2004). Yet these early behaviors suggest that babies are biologically prepared to coordinate hand with eye in the act of exploring.

At about 3 to 4 months, as infants develop the necessary eye, head, and shoulder control, reaching reappears as purposeful, forward arm movements in the presence of a nearby toy and gradually improves in accuracy (Bhat, Heathcock, & Galloway, 2005). By 5 to 6 months, infants reach for an object in a room that has been darkened during the reach by switching off the lights—a skill that improves over the next few months (Clifton

© DON DESPAIN/ALAMY

This West Indian mother of Jamaica “walks” her baby up her body in a deliberate effort to promote early mastery of walking.

**FIGURE 4.12** Some milestones of reaching and grasping. The average age at which each skill is attained is given. (Ages from Bayley, 1969; Rochat, 1989.)

et al., 1994; McCarty & Ashmead, 1999). Early on, vision is freed from the basic act of reaching so it can focus on more complex adjustments. By 7 months, the arms become more independent; infants reach for an object by extending one arm rather than both (Fagard & Pez , 1997). During the next few months, infants become more efficient at reaching for moving objects—ones that spin, change direction, and move sideways, closer, or farther away (Fagard, Spelke, & von Hofsten, 2009; Wentworth, Benson, & Haith, 2000).

Once infants can reach, they modify their grasp. The newborn's grasp reflex is replaced by the *ulnar grasp*, a clumsy motion in which the fingers close against the palm. Still, even 4- to 5-month-olds modify their grasp to suit an object's size, shape, and texture (rigid versus soft)—a capacity that improves over the second half-year as infants adjust the hand more precisely and do so in advance of contacting the object (Rocha et al., 2013; Witherington, 2005). Around 4 to 5 months, when infants begin to sit up, both hands become coordinated in exploring objects. Babies of this age can hold an object in one hand while the other scans it with the fingertips, and they frequently transfer objects from hand to hand (Rochat & Goubet, 1995). By the end of the first year, babies use the thumb and index finger opposably in a well-coordinated *pincer grasp*. Then the ability to manipulate objects greatly expands. The 1-year-old can pick up raisins and blades of grass, turn knobs, and open and close small boxes.

Between 8 and 11 months, reaching and grasping are well-practiced, so attention is released from the motor skill to events that occur before and after attaining the object. For example, 10-month-olds modify their reach to anticipate their next action. They adjust their arm and hand to catch a ball, and they reach for a ball faster when they intend to throw it than when they intend to push it down a narrow tube (Claxton, Keen, & McCarty, 2003; Kaye & Van der Meer, 2009). Around this time, too, infants begin to solve simple problems that involve reaching, such as searching for and finding a hidden toy.

Finally, the capacity to reach for and manipulate an object increases infants' attention to the way an adult reaches for and plays with that same object (Hauf, Aschersleben, & Prinz, 2007). As babies watch what others do, they broaden their understanding of others' behaviors and of the range of actions that can be performed on various objects.

## Ask yourself

**CONNECT** Provide several examples of how motor development influences infants' and toddlers' social experiences. How do social experiences, in turn, influence motor development?

**APPLY** List everyday experiences that support mastery of reaching, grasping, sitting, and crawling. Why should caregivers place young infants in a variety of waking-time body positions?

**REFLECT** Do you favor early, systematic training of infants in motor skills such as crawling, walking, and stair climbing? Why or why not?

## Perceptual Development

**4.7** What changes in hearing, depth and pattern perception, and intermodal perception take place during infancy?

**4.8** Explain differentiation theory of perceptual development.

In Chapter 3, you learned that the senses of touch, taste, smell, and hearing—but not vision—are remarkably well-developed at birth. Now let's turn to a related question: How does perception change over the first year? Our discussion will address hearing and vision, the focus of almost all research. Recall that in

Chapter 3, we used the word *sensation* to talk about these capacities. It suggests a fairly passive process—what the baby’s receptors detect when exposed to stimulation. Now we use the word *perception*, which is active: When we perceive, we organize and interpret what we see.

As we review the perceptual achievements of infancy, you may find it hard to tell where perception leaves off and thinking begins. The research we are about to discuss provides an excellent bridge to the topic of Chapter 5—cognitive development during the first two years.

## Hearing

On Timmy’s first birthday, Vanessa downloaded nursery songs into a tablet and played one each afternoon at naptime. Soon Timmy let her know his favorite tune. If she put on “Twinkle, Twinkle,” he stood up in his crib and whimpered until she replaced it with “Jack and Jill.” Timmy’s behavior illustrates the greatest change in hearing over the first year of life: Babies start to organize sounds into complex patterns.

Between 4 and 7 months, infants display a sense of musical phrasing: They prefer Mozart minuets with pauses between phrases to those with awkward breaks (Krumhansl & Jusczyk, 1990). Around 6 to 7 months, they can distinguish musical tunes on the basis of variations in rhythmic patterns, including beat structure (duple or triple) and accent structure (emphasis on the first note of every beat unit or at other positions) (Hannon & Johnson, 2004). They are also sensitive to features conveying the purpose of familiar types of songs, preferring to listen to high-pitched playsongs (aimed at entertaining) and low-pitched lullabies (used to soothe) (Tsang & Conrad, 2010). By the end of the first year, infants recognize the same melody when it is played in different keys (Trehub, 2001). As we will see next, 6- to 12-month-olds make comparable discriminations in human speech: They readily detect sound regularities, which facilitates later language learning.

**Speech Perception.** Recall from Chapter 3 that newborns can distinguish nearly all sounds in human languages and that they prefer listening to human speech over nonspeech sounds and to their native tongue rather than a rhythmically distinct foreign language. Brain-imaging evidence reveals that in young infants, discrimination of speech sounds activates both auditory and motor areas in the cerebral cortex (Kuhl et al., 2014). Researchers speculate that while perceiving speech sounds, babies also generate internal motor plans that prepare them for producing those sounds.

As infants listen to people talk, they learn to focus on meaningful sound variations. ERP brain-wave recordings reveal that around 5 months, infants become sensitive to syllable stress patterns in their own language (Weber et al., 2004). Between 6 and 8 months, they start to “screen out” sounds not used in their native tongue and, in the case of bilingual infants, in both native languages (Albareda-Castellot, Pons, & Sebastián-Gallés, 2010;

Curtin & Werker, 2007). As the Biology and Environment box on the following page explains, this increased responsiveness to native-language sounds is part of a general “tuning” process in the second half of the first year—a possible sensitive period in which infants acquire a range of perceptual skills for picking up socially important information.

Soon after, infants focus on larger speech units that are critical to figuring out meaning. They recognize familiar words in spoken passages and listen longer to speech with clear clause and phrase boundaries (Johnson & Seidl, 2008; Jusczyk & Hohne, 1997; Soderstrom et al., 2003). Around 7 to 9 months, infants extend this sensitivity to speech structure to individual words: They begin to divide the speech stream into wordlike units (Jusczyk, 2002; MacWhinney, 2015).

**Analyzing the Speech Stream.** How do infants make such rapid progress in perceiving the structure of speech? Research shows that they have an impressive **statistical learning capacity**. By analyzing the speech stream for patterns—repeatedly occurring sequences of sounds—they acquire a stock of speech structures for which they will later learn meanings, long before they start to talk around age 12 months.

For example, when presented with controlled sequences of nonsense syllables, babies as young as 5 months listen for

© LAURA DWIGHT PHOTOGRAPHY

A 6-month-old is a remarkable analyzer of the speech stream. While listening to her mother talk, she detects sound patterns, discriminating words and word sequences for which she will later learn meanings.

## Biology and Environment

### “Tuning In” to Familiar Speech, Faces, and Music: A Sensitive Period for Culture-Specific Learning

To share experiences with members of their family and community, babies must become skilled at making perceptual discriminations that are meaningful in their culture. As we have seen, at first babies are sensitive to virtually all speech sounds, but around 6 months, they narrow their focus, limiting the distinctions they make to the language they hear and will soon learn.

The ability to perceive faces shows a similar **perceptual narrowing effect**—perceptual sensitivity that becomes increasingly attuned with age to information most often encountered. After habituating to one member of each pair of faces in Figure 4.13, 6-month-olds were shown the familiar face and the novel face side by side. For both pairs, they recovered to (looked longer at) the novel face, indicating that they could discriminate individual faces of both humans and monkeys equally well (Pascalis, de Haan, & Nelson, 2002). But at 9 months, infants no longer showed a novelty preference when viewing the monkey pair. Like adults, they could distinguish only the human faces. Similar findings emerge with sheep faces: Four- to 6-month-olds easily distinguish them, but 9- to 11-month-olds no longer do (Simpson et al., 2011).

This perceptual narrowing effect appears again in musical rhythm perception. Western adults are accustomed to the even-beat pattern of Western music—repetition of the same rhythmic structure in every measure of a tune—and easily notice rhythmic changes that disrupt this familiar beat. But present them with music that does not follow this typical Western rhythmic form—Baltic folk tunes, for example—and they fail to pick up on rhythmic-pattern deviations. In contrast, 6-month-olds can detect such disruptions in

both Western and non-Western melodies. By 12 months, however, after added exposure to Western music, babies are no longer aware of deviations in foreign musical rhythms, although their sensitivity to Western rhythmic structure remains unchanged (Hannon & Trehub, 2005b).

Several weeks of regular interaction with a foreign-language speaker and of daily opportunities to listen to non-Western music fully restore 12-month-olds’ sensitivity to wide-ranging speech sounds and music rhythms (Hannon & Trehub, 2005a; Kuhl, Tsao, & Liu, 2003). Similarly, 6-month-olds given three months of training in discriminating individual monkey faces, in which each image is labeled with a distinct name (“Carlos,” “Iona”) instead of the generic label “monkey,” retain their ability to discriminate monkey faces at 9 months (Scott & Monesson, 2009). Adults given similar extensive experiences, by contrast, show little improvement in perceptual sensitivity.

Taken together, these findings suggest a heightened capacity—or sensitive period—in the second half of the first year, when babies are biologically prepared to “zero in” on socially meaningful perceptual distinctions. Notice how, between 6 and 12 months,

**FIGURE 4.13** Discrimination of human and monkey faces.

Which of these pairs is easiest for you to tell apart? After habituating to one of the photos in each pair, infants were shown the familiar and the novel face side by side. For both pairs, 6-month-olds recovered to (looked longer at) the novel face, indicating that they could discriminate human and monkey faces equally well. By 12 months, babies lost their ability to distinguish the monkey faces. Like adults, they showed a novelty preference only to human stimuli. (From O. Pascalis et al., 2002, “Is Face Processing Species-Specific During the First Year of Life?” *Science*, 296, p. 1322. Copyright © 2002 by AAAS. Republished with permission of American Association for the Advancement of Science conveyed through Copyright Clearance Center, Inc.)

learning is especially rapid across several domains (speech, faces, and music) and is easily modified by experience. This suggests a broad neurological change—perhaps a special time of experience-expectant brain growth (see page 124) in which babies analyze stimulation of all kinds in ways that prepare them to participate in their cultural community.

statistical regularities: They locate words by distinguishing syllables that often occur together (indicating they belong to the same word) from syllables that seldom occur together (indicating a word boundary) (Johnson & Tyler, 2010). Consider the English word sequence *pretty#baby*. After listening to the speech stream

for just one minute (about 60 words), babies can distinguish a word-internal syllable pair (*pretty*) from a word-external syllable pair (*ty#ba*). They prefer to listen to new speech that preserves the word-internal pattern (Saffran, Aslin, & Newport, 1996; Saffran & Thiessen, 2003).

Once infants begin locating words, they focus on the words and, around 7 to 8 months, identify regular syllable-stress patterns—for example, in English, that the onset of a strong syllable (*hap-py, rab-bit*) often signals a new word (Thiessen & Saffran, 2007). By 10 months, babies can detect words that start with weak syllables, such as “*surprise*,” by listening for sound regularities before and after the words (Kooijman, Hagoort, & Cutler, 2009).

Clearly, babies have a powerful ability to extract patterns from complex, continuous speech. Their remarkable statistical learning capacity also extends to visual stimuli and is present in the first weeks of life (Aslin & Newport, 2012). Statistical learning seems to be a general capacity that infants use to analyze complex stimulation.

Finally, the more rapidly 10-month-olds detect words within the speech stream (as indicated by ERP recordings), the larger their vocabulary at age 2 years (Junge et al., 2012). Parents’ speech to babies, which often contains single-word utterances followed by the same words embedded in the speech stream (“Doggie!” “See the big doggie?”), aids word discrimination (Lew-Williams, Pelucchi, & Saffran, 2011). As we will see in Chapter 5, adults’ style of communicating with infants greatly facilitates analysis of the structure of speech.

## Vision

For exploring the environment, humans depend on vision more than any other sense. Although at first a baby’s visual world is fragmented, it undergoes extraordinary changes during the first 7 to 8 months of life.

Visual development is supported by rapid maturation of the eye and visual centers in the cerebral cortex. Recall from Chapter 3 that the newborn baby focuses and perceives color poorly. Around 2 months, infants can focus on objects about as well as adults can, and their color vision is adultlike by 4 months (Johnson & Hannon, 2015). *Visual acuity* (fineness of discrimination) increases steadily, reaching 20/80 by 6 months and an adult level of about 20/20 by 4 years (Slater et al., 2010). Scanning the environment and tracking moving objects also improve over the first half-year as infants better control their eye movements and build an organized perceptual world (Johnson, Slemmer, & Amso, 2004; von Hofsten & Rosander, 1998).

As babies explore their visual field, they figure out the characteristics of objects and how they are arranged in space. To understand how they do so, let’s examine the development of two aspects of vision: depth and pattern perception.

**Depth Perception.** *Depth perception* is the ability to judge the distance of objects from one another and from ourselves. It is important for understanding the layout of the environment and for guiding motor activity.

Figure 4.14 shows the *visual cliff*, designed by Eleanor Gibson and Richard Walk (1960) and used in the earliest studies of depth perception. It consists of a Plexiglas-covered table with

© MARK RICHARDS/PHOTOFEST

**FIGURE 4.14** The visual cliff. Plexiglas covers the deep and shallow sides. By refusing to cross the deep side and showing a preference for the shallow side, this infant demonstrates the ability to perceive depth.

a platform at the center, a “shallow” side with a checkerboard pattern just under the glass, and a “deep” side with a checkerboard pattern several feet below the glass. The researchers found that crawling babies readily crossed the shallow side, but most avoided the deep side. They concluded that around the time infants crawl, most distinguish deep from shallow surfaces and steer clear of drop-offs.

The visual cliff shows that crawling and avoidance of drop-offs are linked, but not how they are related or when depth perception first appears. Subsequent research has looked at babies’ ability to detect specific depth cues, using methods that do not require that they crawl.

*Motion* is the first depth cue to which infants are sensitive. Babies 3 to 4 weeks old blink their eyes defensively when an object moves toward their face as if it is going to hit (Náñez & Yonas, 1994). *Binocular depth cues* arise because our two eyes have slightly different views of the visual field. The brain blends these two images, resulting in perception of depth. Research in which two overlapping images are projected before the baby,

who wears special goggles to ensure that each eye receives only one image, reveals that sensitivity to binocular cues emerges between 2 and 3 months and improves rapidly over the first year (Brown & Miracle, 2003). Finally, beginning at 3 to 4 months and strengthening between 5 and 7 months, babies display sensitivity to *pictorial depth cues*—the ones artists often use to make a painting look three-dimensional. Examples include receding lines that create the illusion of perspective, changes in texture (nearby textures are more detailed than faraway ones), overlapping objects (an object partially hidden by another object is perceived to be more distant), and shadows cast on surfaces (indicating a separation in space between the object and the surface) (Kavšek, Yonas, & Granrud, 2012).

Why does perception of depth cues emerge in the order just described? Researchers speculate that motor development is involved. For example, control of the head during the early weeks of life may help babies notice motion and binocular cues. Around 5 to 6 months, the ability to turn, poke, and feel the surface of objects promotes perception of pictorial cues (Bushnell & Boudreau, 1993; Soska, Adolph, & Johnson, 2010). And as we will see next, one aspect of motor progress—independent movement—plays a vital role in refinement of depth perception.

**Independent Movement and Depth Perception.** At 6 months, Timmy started crawling. “He’s fearless!” exclaimed Vanessa. “If I put him down in the middle of my bed, he crawls right over the edge. The same thing happens by the stairs.” Will Timmy become wary of the side of the bed and the staircase as he becomes a more experienced crawler? Research suggests that he will. Infants with more crawling experience (regardless of when they started to crawl) are far more likely to refuse to cross the deep side of the visual cliff (Campos et al., 2000).

From extensive everyday experience, babies gradually figure out how to use depth cues to detect the danger of falling. But because the loss of body control that leads to falling differs greatly for each body position, babies must undergo this learning separately for each posture (Adolph & Kretch, 2012). In one study, 9-month-olds who were experienced sitters but novice crawlers were placed on the edge of a shallow drop-off that could be widened (Adolph, 2008). While in the familiar sitting position, infants avoided leaning out for an attractive toy at distances likely to result in falling. But in the unfamiliar crawling posture, they headed over the edge, even when the distance was extremely wide! And newly walking babies will step repeatedly over a risky drop-off (Kretch & Adolph, 2013). They will also careen down slopes and over uneven surfaces without making necessary postural adjustments (Adolph et al., 2008; Joh & Adolph, 2006). Thus, they fall frequently. As infants and toddlers discover how to avoid falling in different postures and situations, their understanding of depth expands.

Independent movement promotes other aspects of three-dimensional understanding. For example, seasoned crawlers are better than their inexperienced agemates at remembering object locations and finding hidden objects (Campos et al., 2000). They

© ELLEN B. SENISI

As this 8-month-old becomes adept at crawling, his experience fosters three-dimensional understanding—for example, remembering object locations and how objects appear from different viewpoints.

are also better at recognizing the identity of a previously viewed moving object when shown that object from a new angle (Schwarzer, Freitag, & Schum, 2013).

Why does crawling make such a difference? Compare your own experience of the environment when you are driven from one place to another with what you experience when you walk or drive yourself. When you move on your own, you are much more aware of landmarks and routes of travel, and you take more careful note of what things look like from different points of view. The same is true for infants. In fact, crawling promotes a new level of brain organization, as indicated by more organized EEG brain-wave activity in the cerebral cortex (Bell & Fox, 1996). Perhaps crawling strengthens certain neural connections, especially those involved in vision and understanding of space.

**Pattern Perception.** Even newborns prefer to look at patterned rather than plain stimuli (Fantz, 1961). As they get older, infants prefer more complex patterns. For example, 3-week-olds look longest at black-and-white checkerboards with a few large squares, whereas 8- and 14-week-olds prefer those with many squares (Brennan, Ames, & Moore, 1966).

A general principle, called **contrast sensitivity**, explains early pattern preferences (Banks & Ginsburg, 1985). *Contrast* refers to the difference in the amount of light between adjacent

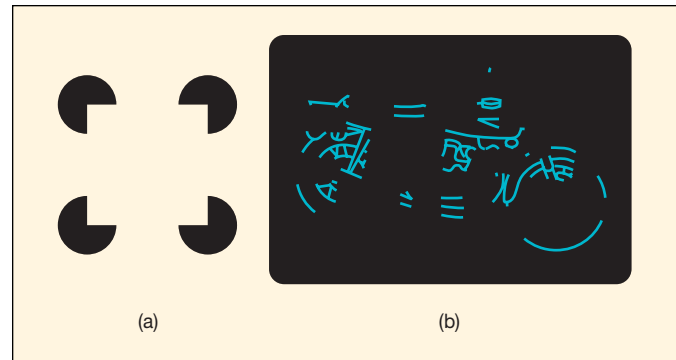

**FIGURE 4.15** The way two checkerboards differing in complexity look to infants in the first few weeks of life. Because of their poor vision, very young infants cannot resolve the fine detail in the *complex checkerboard*. It appears blurred, like a gray field. The large, *bold checkerboard* appears to have more contrast, so babies prefer to look at it. (Adapted from M. S. Banks & P. Salapatek, 1983, “Infant Visual Perception,” in M. M. Haith & J. J. Campos [Eds.], *Handbook of Child Psychology: Vol. 2. Infancy and Developmental Psychology* [4th ed.]. New York: John Wiley & Sons, p. 504. Copyright © 1983 by John Wiley & Sons, Inc. Reproduced with permission of John Wiley & Sons, Inc.)

regions in a pattern. If babies are *sensitive to* (can detect) the contrast in two or more patterns, they prefer the one with more contrast. To understand this idea, look at the checkerboards in the top row of Figure 4.15. To us, the one with many small squares has more contrasting elements. Now look at the bottom row, which shows how these checkerboards appear to infants in the first few weeks of life. Because of their poor vision, very young babies cannot resolve the small features in more complex patterns, so they prefer to look at the large, bold checkerboard. Around 2 months, when detection of fine-grained detail has improved, infants become sensitive to the contrast in complex patterns and spend more time looking at them (Gwiazda & Birch, 2001).

In the early weeks of life, infants respond to the separate parts of a pattern. They stare at single high-contrast features, generally on the edges, and have difficulty shifting their gaze away toward other interesting stimuli (Hunnus & Geuze, 2004a, 2004b). At 2 to 3 months, when scanning ability and contrast sensitivity improve, infants thoroughly explore a pattern’s features, pausing briefly to look at each part (Bronson, 1994).

Once babies can take in all aspects of a pattern, they integrate the parts into a unified whole. Around 4 months, babies are so good at detecting pattern organization that they perceive subjective boundaries that are not really present. For example, they

**FIGURE 4.16** Subjective boundaries in visual patterns. (a) Do you perceive a square in the middle of the figure? By 4 months of age, infants do, too. (b) What does the image, missing two-thirds of its outline, look like to you? By 12 months, infants detect a motorcycle. After habituating to the incomplete motorcycle image, they were shown an intact motorcycle figure paired with a novel form. Twelve-month-olds recovered to (looked longer at) the novel figure, indicating that they recognized the motorcycle pattern on the basis of very little visual information. (Adapted from Ghim, 1990; Rose, Jankowski, & Senior, 1997.)

perceive a square in the center of Figure 4.16a, just as you do (Ghim, 1990). Older infants carry this sensitivity to subjective form further, applying it to complex, moving stimuli. For example, 9-month-olds look much longer at an organized series of blinking lights that resembles a human being walking than at an upside-down or scrambled version (Bertenthal, 1993). At 12 months, infants detect familiar objects represented by incomplete drawings, even when as much as two-thirds of the drawing is missing (see Figure 4.16b) (Rose, Jankowski, & Senior, 1997). As these findings reveal, infants’ increasing knowledge of objects and actions supports pattern perception.

**Face Perception.** Infants’ tendency to search for structure in a patterned stimulus also applies to face perception. Newborns prefer to look at photos and simplified drawings of faces with features arranged naturally (upright) rather than unnaturally (upside-down or sideways) (see Figure 4.17a) (Cassia, Turati, & Simion, 2004; Mondloch et al., 1999). They also track a facelike pattern moving across their visual field farther than they track other stimuli (Johnson, 1999). And although they rely more on outer features (hairline and chin) than inner features to distinguish real faces, newborns prefer photos of faces with eyes open and a direct gaze (Farroni et al., 2002; Turati et al., 2006). Yet another amazing capacity is their tendency to look longer at both human and animal faces judged by adults as attractive—a preference that may be the origin of the widespread social bias favoring physically attractive people (Quinn et al., 2008; Slater et al., 2010).

Some researchers claim that these behaviors reflect a built-in capacity to orient toward members of one’s own species, just as many newborn animals do (Johnson, 2001; Slater et al., 2011). Others assert that newborns prefer any stimulus in which the most salient elements are arranged horizontally in the upper part of a pattern—like the “eyes” in Figure 4.17b (Cassia, Turati, & Simion, 2004). Possibly, however, a bias favoring the facial

pattern promotes such preferences. Still other researchers argue that newborns are exposed to faces more often than to other stimuli—early experiences that could quickly “wire” the brain to detect faces and prefer attractive ones (Bukacha, Gauthier, & Tarr, 2006).

Although newborns respond to facelike structures, they cannot discriminate a stationary, complex facial pattern from other, equally complex patterns (see Figure 4.17c). But from repeated exposures to their mother’s face, they quickly learn to prefer her face to that of an unfamiliar woman, although they mostly attend to its broad outlines. Around 2 months, when they can combine pattern elements into an organized whole, babies prefer a complex drawing of the human face to other equally complex stimulus arrangements (Dannemiller & Stephens, 1988). And they clearly prefer their mother’s detailed facial features to those of another woman (Bartrip, Morton, & de Schonen, 2001).

Around 3 months, infants make fine distinctions among the features of different faces—for example, between photographs

**FIGURE 4.17 Early face perception.** Newborns prefer to look at the photo of a face (a) and the simple pattern resembling a face (b) over the upside-down versions. (c) When the complex drawing of a face on the left and the equally complex, scrambled version on the right are moved across newborns’ visual field, they follow the face longer. But if the two stimuli are stationary, infants show no preference for the face until around 2 months of age. (From Cassia, Turati, & Simion, 2004; Johnson, 1999; Mondloch et al., 1999.)

of two strangers, even when the faces are moderately similar (Farroni et al., 2007). At 5 months—and strengthening over the second half-year—infants perceive emotional expressions as meaningful wholes. They treat positive faces (happy and surprised) as different from negative ones (sad and fearful) (Bornstein & Arterberry, 2003). And by 7 months, they discriminate among a wider range of facial expressions, including happiness, surprise, sadness, fearfulness, and anger (Witherington et al., 2010).

Experience influences face processing, leading babies to form group biases at a tender age. As early as 3 months, infants prefer and more easily discriminate among female faces than among male faces (Ramsey-Rennels & Langlois, 2006). The greater time infants spend with female adults explains this effect, since babies with a male primary caregiver prefer male faces. Furthermore, 3- to 6-month-olds exposed mostly to members of their own race prefer to look at the faces of members of that race, and between 6 and 9 months their ability to discriminate other-race faces weakens (Kelly et al., 2007, 2009). This own-race bias is absent in babies who have frequent contact with members of other races, and it can be reversed through exposure to racial diversity (Anzures et al., 2013; Heron-Delaney et al., 2011). Notice how early experience promotes *perceptual narrowing* with respect to gender and racial information in faces, as occurs for species information, discussed in the Biology and Environment box on page 139.

Development of areas specialized for face processing in the right cerebral hemisphere plus extensive face-to-face interaction with caregivers contribute to infants’ refinement of face perception. Face identification continues to improve throughout childhood (Stiles et al., 2015). Not until ages 10 to 11 are children as adept as adults at rapidly and accurately discriminating highly similar faces encountered in everyday life.

Up to this point, we have considered the infant’s sensory systems one by one. Now let’s examine their coordination.

## Intermodal Perception

Our world provides rich, continuous *intermodal stimulation*—simultaneous input from more than one *modality*, or sensory system. In **intermodal perception**, we make sense of these running streams of light, sound, tactile, odor, and taste information, perceiving them as integrated wholes. We know, for example, that an object’s shape is the same whether we see it or touch it, that lip movements are closely coordinated with the sound of a voice, and that dropping a rigid object on a hard surface will cause a sharp, banging sound.

Recall that newborns turn in the general direction of a sound and reach for objects in a primitive way. These behaviors suggest that infants expect sight, sound, and touch to go together. Research reveals that babies perceive input from different sensory systems in a unified way by detecting *amodal sensory properties*—information that overlaps two or more sensory systems, such as rate, rhythm, duration, intensity, temporal synchrony (for vision and hearing), and texture and shape (for vision and touch). Consider the sight and sound of a bouncing ball or

© LAURA DWIGHT PHOTOGRAPHY

This toddler exploring a tambourine readily detects amodal relations in the synchronous sounds and visual appearance of its metal jingles.

the face and voice of a speaking person. In each event, visual and auditory information occur simultaneously and with the same rate, rhythm, duration, and intensity.

Even newborns are impressive perceivers of amodal properties. After touching an object (such as a cylinder) placed in their palms, they recognize it visually, distinguishing it from a different-shaped object (Sann & Streri, 2007). And they require just one exposure to learn the association between the sight and sound of a toy, such as a rhythmically jangling rattle (Morrongiello, Fenwick, & Chance, 1998).

Within the first half-year, infants master a remarkable range of intermodal relationships. Three- to 5-month-olds can match faces with voices on the basis of lip–voice synchrony, emotional expression, and even age and gender of the speaker. Around 6 months, infants can perceive and remember the unique face–voice pairings of unfamiliar adults (Flom, 2013).

How does intermodal perception develop so quickly? Young infants seem biologically primed to focus on amodal information. Their detection of amodal relations—for example, the common tempo and rhythm in sights and sounds—precedes and provides the basis for detecting more specific intermodal matches, such as the relation between a particular person’s face and the sound of her voice or between an object and its verbal label (Bahrick, 2010).

Intermodal sensitivity is crucial for perceptual development. In the first few months, when much stimulation is unfamiliar and confusing, it enables babies to notice meaningful correlations between sensory inputs and rapidly make sense of their surroundings.

In addition to easing perception of the physical world, intermodal perception facilitates social and language processing. For example, as 3- to 4-month-olds gaze at an adult’s face, they initially require both vocal and visual input to distinguish positive from negative emotional expressions (Flom & Bahrick, 2007). Only later do infants discriminate positive from negative emotion

in each sensory modality—first in voices (around 5 months), then (from 7 months on) in faces (Bahrick, Hernandez-Reif, & Flom, 2005). Furthermore, in speaking to infants, parents often provide temporal synchrony between words, object motions, and touch—for example, saying “doll” while moving a doll and having it touch the infant. This greatly increases the chances that babies will remember the association between the word and the object (Gogate & Bahrick, 2001).

## LOOK and LISTEN

While watching a parent and infant playing, list instances of parental intermodal stimulation and communication. What is the baby likely learning about people, objects, or language from each intermodal experience?

In sum, intermodal perception fosters all aspects of psychological development. When caregivers provide many concurrent sights, sounds, and touches, babies process more information and learn faster (Bahrick, 2010). Intermodal perception is yet another fundamental capacity that assists infants in their active efforts to build an orderly, predictable world.

## Understanding Perceptual Development

Now that we have reviewed the development of infant perceptual capacities, how can we put together this diverse array of amazing achievements? Widely accepted answers come from the work of Eleanor and James Gibson. According to the Gibsons’ **differentiation theory**, infants actively search for *invariant features* of the environment—those that remain stable—in a constantly changing perceptual world. In pattern perception, for example, young babies search for features that stand out and orient toward faces. Soon they explore internal features, noticing *stable relationships* among them. As a result, they detect patterns, such as complex designs and individual faces. Similarly, infants analyze the speech stream for regularities, detecting words, word-order sequences, and—within words—syllable-stress patterns. The development of intermodal perception also reflects this principle (Bahrick & Lickliter, 2012). Babies seek out invariant relationships—first, amodal properties, such as common rate and rhythm in a voice and face, and later more detailed associations, such as unique voice–face matches.

The Gibsons described their theory as *differentiation* (where *differentiate* means “analyze” or “break down”) because over time, the baby detects finer and finer invariant features among stimuli. In addition to pattern perception and intermodal perception, differentiation applies to depth perception. Recall how sensitivity to motion precedes detection of fine-grained pictorial features. So one way of understanding perceptual development is to think of it as a built-in tendency to seek order and consistency—a capacity that becomes increasingly fine-tuned with age (Gibson, 1970; Gibson, 1979).

© ELLEN B. SENISI

© ELLEN B. SENISI

Babies' changing motor skills transform the way they perceive surfaces. *Left photo:* A 12-month-old who has just begun to walk proceeds feet-first down a steep incline, unaware of the high risk of falling. *Right photo:* An 18-month-old with extensive experience walking knows that it's best to sit and scoot down the incline.

Infants constantly look for ways in which the environment *affords possibilities for action* (Gibson, 2003). By exploring their surroundings, they figure out which objects can be grasped, squeezed, bounced, or stroked and which surfaces are safe to cross or present the possibility of falling. And from handling objects, babies become more aware of a variety of observable object properties (Perone et al., 2008). As a result, they differentiate the world in new ways and act more competently.

To illustrate, recall how infants' changing capabilities for independent movement affect their perception. When babies crawl, and again when they walk, they gradually realize that a sloping surface *affords the possibility of falling*. With added weeks of practicing each skill, they hesitate to crawl or walk down a risky incline. Experience in trying to keep their balance on various surfaces makes crawlers and walkers more aware of the consequences of their movements. Crawlers come to detect when surface slant places so much body weight on their arms that they will fall forward, and walkers come to sense when an incline shifts body weight so their legs and feet can no longer hold them upright.

Infants do not transfer their learning about slopes or drop-offs from crawling to walking because the affordances for each posture are different (Adolph, Kretch, & LoBue, 2014). Learning is gradual and effortful because newly crawling and walking babies cross many types of surfaces in their homes each day. As they experiment with balance and postural adjustments to accommodate each, they perceive surfaces in new ways that guide their movements. As a result, they act more competently.

As we conclude our discussion of infant perception, it is only fair to note that some researchers believe that babies do more than make sense of experience by searching for invariant features and action possibilities: They also *impose meaning* on what they perceive, constructing categories of objects and events in the surrounding environment (Johnson & Hannon, 2015). We have seen the glimmerings of this *cognitive* point of view in this chapter. For example, older babies *interpret* a familiar face as a source of pleasure and affection and a pattern of blinking lights as a human being walking. This cognitive perspective also has merit in understanding the achievements of infancy. In fact, many researchers combine these two positions, regarding infant development as proceeding from a perceptual to a cognitive emphasis over the first year of life.

## Ask yourself

**CONNECT** Using examples, explain why intermodal perception is vital for infants' developing understanding of their physical and social worlds.

**APPLY** After several weeks of crawling, Ben learned to avoid going headfirst over a drop-off. Now he has started to walk. Can his parents trust him not to step over a risky drop-off? Explain, using the concept of affordances.

**REFLECT** Consider a new motor skill that you acquired. How do you think it changed your perceptual and cognitive capacities?

## Summary / chapter 4

### Body Growth (p. 116)

#### 4.1 Describe major changes in body growth over the first two years.

- Height and weight gains are greater during the first two years than at any other time after birth. Body fat increases quickly during the first nine months, whereas muscle development is slow and gradual. Body proportions change as growth follows the **cephalocaudal** and **proximodistal** trends.

### Brain Development (p. 117)

#### 4.2 Describe brain development during infancy and toddlerhood, current methods of measuring brain functioning, and appropriate stimulation to support the brain's potential.

- Early in development, the brain grows faster than any other organ of the body. Once **neurons** are in place, they rapidly extend fibers to form **synapses**. Neurons release chemicals called **neurotransmitters**, which cross synapses to communicate with other neurons. **Programmed cell death** makes space for neural fibers and synapses. Seldom stimulated neurons lose their synapses in a process called **synaptic pruning**. **Glial cells**, responsible for **myelination**, multiply rapidly through the second year, contributing to large gains in brain weight.
- Measures of brain functioning include those that detect changes in electrical activity in the cerebral cortex (EEG, ERPs), neuroimaging techniques (PET, fMRI), and NIRS, an imaging technique suitable for infants and young children.
- The **cerebral cortex** is the largest, most complex brain structure and the last to stop growing. Its frontal lobes contain the **prefrontal cortex**, which is responsible for complex thought. Gradually, the hemispheres of the cerebral cortex specialize, a process called **lateralization**. But in the first few years of life, there is high **brain plasticity**: Many areas are not yet committed to specific functions, and the capacity for learning is high.
- Both heredity and early experience contribute to brain organization. Stimulation of the brain is essential during sensitive periods, when the brain is developing most rapidly. Prolonged early deprivation can disrupt development of the cerebral cortex, especially the prefrontal cortex, and interfere with the brain's capacity to manage stress, with long-term physical and psychological consequences.

- Appropriate early stimulation promotes **experience-expectant brain growth**, which depends on ordinary experiences. No evidence exists for a sensitive period in the first few years for **experience-dependent brain growth**, which relies on specific learning experiences. In fact, environments that overwhelm children with inappropriately advanced expectations can undermine the brain's potential.

#### 4.3 How does the organization of sleep and wakefulness change over the first two years?

- Infants' changing arousal patterns are primarily affected by brain growth, but the social environment also plays a role. Periods of sleep and wakefulness become fewer but longer, increasingly conforming to a night–day schedule.
- Most parents in Western nations try to get their babies to sleep through the night much earlier than parents throughout most of the world, who are more likely to sleep with their babies. Regular bedtime routines promote sleep in infants and toddlers.

### Influences on Early Physical Growth (p. 127)

#### 4.4 Cite evidence that heredity and nutrition both contribute to early physical growth.

- Twin and adoption studies reveal that heredity contributes to body size and rate of physical growth.
- Breast milk is ideally suited to infants' growth needs. Breastfeeding protects against disease and prevents malnutrition and infant death in poverty-stricken areas of the world.
- Most infants and toddlers can eat nutritious foods freely without risk of becoming overweight. However, the relationship between rapid weight gain in infancy and later obesity is strengthening because of the rise in unhealthy parental feeding practices.

- **Marasmus** and **kwashiorkor**, two dietary diseases caused by malnutrition, affect many children in developing countries. If prolonged, they can permanently stunt body growth and brain development.

### Learning Capacities (p. 130)

#### 4.5 Describe infant learning capacities, the conditions under which they occur, and the unique value of each.

- **Classical conditioning** is based on the infant's ability to associate events that usually occur together in the everyday world. Infants can be classically conditioned most easily when the pairing of an **unconditioned stimulus (UCS)** and a **conditioned stimulus (CS)** has survival value.
- In **operant conditioning**, infants act on the environment, and their behavior is followed by either **reinforcers**, which increase the occurrence of a preceding behavior, or **punishment**, which either removes a desirable stimulus or presents an unpleasant one to decrease the occurrence of a response. In young infants, interesting sights and sounds and pleasurable caregiver interaction serve as effective reinforcers.
- **Habituation** and **recovery** reveal that at birth, babies are attracted to novelty. Novelty preference (recovery to a novel stimulus) assesses recent memory, whereas familiarity preference (recovery to the familiar stimulus) assesses remote memory.
- Newborns have a primitive ability to imitate adults' facial expressions and gestures. **Imitation** is a powerful means of learning, which contributes to the parent–infant bond. Scientists have identified specialized cells called **mirror neurons** that may underlie infants' capacity to imitate.

### Motor Development (p. 133)

#### 4.6 Describe dynamic systems theory of motor development, along with factors that influence motor progress in the first two years.

- According to **dynamic systems theory of motor development**, children acquire new motor skills by combining existing skills into increasingly complex systems of action. Each new skill is a joint product of central nervous system development, the body's movement possibilities, the child's goals, and environmental supports for the skill.

- Movement opportunities and a stimulating environment profoundly affect motor development, as shown by observations of infants learning to crawl and walk in varying contexts. Cultural values and child-rearing customs also contribute to the emergence and refinement of motor skills.

© DON DESPAIN/ALAMY

- During the first year, infants perfect reaching and grasping. Reaching gradually becomes more accurate and flexible, and the clumsy ulnar grasp is transformed into a refined pincer grasp.

## Perceptual Development (p. 137)

### 4.7 What changes in hearing, depth and pattern perception, and intermodal perception take place during infancy?

- Infants organize sounds into increasingly complex patterns and, as part of the **perceptual narrowing effect**, begin to “screen out” sounds not used in their native language by the middle of the first year. An impressive **statistical learning capacity** enables babies to detect regular sound patterns, for which they will later learn meanings.

- Rapid maturation of the eye and visual centers in the brain supports the development of focusing, color discrimination, and visual acuity during the first half-year. The ability to scan the environment and track moving objects also improves.

- Research on depth perception reveals that responsiveness to motion cues develops first, followed by sensitivity to binocular and then to pictorial cues. Experience in independent movement enhances depth perception and other aspects of three-dimensional understanding, but babies must learn to avoid drop-offs for each body position.

- **Contrast sensitivity** explains infants’ early pattern preferences. At first, babies stare at single, high-contrast features. Over time, they discriminate increasingly complex, meaningful patterns.

- Newborns prefer to look at and track simple, facelike stimuli, but researchers disagree on whether they have a built-in tendency to orient toward human faces. Around 2 months, they prefer their mother’s facial features; at 3 months, they distinguish the features of different faces; and by 7 months, they discriminate various facial expressions, including happiness, sadness, and surprise.

© LAURA DWIGHT PHOTOGRAPHY

### 4.8 Explain differentiation theory of perceptual development.

- According to **differentiation theory**, perceptual development is a matter of detecting invariant features in a constantly changing perceptual world. Acting on the world plays a major role in perceptual differentiation. From a cognitive perspective, infants also impose meaning on what they perceive. Many researchers combine these two ideas.

When Caitlin, Grace, and Timmy gathered at Ginette's child-care home, the playroom was alive with activity. The three spirited explorers, each nearly 18 months old, were bent on discovery. Grace dropped shapes through holes in a plastic box that Ginette held and adjusted so the harder ones would fall smoothly into place. Once a few shapes were inside, Grace grabbed the box and shook it, squealing with delight as the lid fell open and the shapes scattered around her. The clatter attracted Timmy, who picked up a shape, carried it to the railing at the top of the basement steps, and dropped it overboard, then followed with a teddy bear, a ball, his shoe, and a spoon. Meanwhile, Caitlin pulled open a drawer, unloaded a set of wooden bowls, stacked them in a pile, knocked it over, and then banged two bowls together.

As the toddlers experimented, I could see the beginnings of spoken language—a whole new way of influencing the world. “All gone baw!” Caitlin exclaimed as Timmy tossed the bright red ball down the basement steps. “Bye-bye,” Grace chimed in, waving as the ball disappeared from sight. Later that day, Grace revealed the beginnings of make-believe. “Night-night,” she said, putting her head down and closing her eyes, ever so pleased that she could decide for herself when and where to go to bed.

Over the first two years, the small, reflexive newborn baby becomes a self-assertive, purposeful being who solves simple problems and starts to master the most amazing human ability: language. Parents wonder, how does all this happen so quickly? This question has also captivated researchers, yielding a wealth of findings along with vigorous debate over how to explain the astonishing pace of infant and toddler cognitive development.

In this chapter, we take up three perspectives: Piaget's *cognitive-developmental theory*, *information processing*, and Vygotsky's *sociocultural theory*. We also consider the usefulness of tests that measure infants' and toddlers' intellectual progress. Finally, we look at the beginnings of language. We will see how toddlers' first words build on early cognitive achievements and how, very soon, new words and expressions greatly increase the speed and flexibility of their thinking. Throughout development, cognition and language mutually support each other. ●

## Piaget's Cognitive-Developmental Theory

- 5.1** According to Piaget, how do schemes change over the course of development?
- 5.2** Describe major cognitive attainments of the sensorimotor stage.
- 5.3** What does follow-up research say about infant cognitive development and the accuracy of Piaget's sensorimotor stage?

Swiss theorist Jean Piaget inspired a vision of children as busy, motivated explorers whose thinking develops as they act directly on the environment. Influenced by his background in biology, Piaget believed that the child's mind forms and modifies psychological structures so they achieve a better fit with external reality. Recall from Chapter 1 that in Piaget's theory, children move through four stages between infancy and adolescence. During these stages, all aspects of cognition develop in an integrated fashion, changing in a similar way at about the same time.

Piaget's **sensorimotor stage** spans the first two years of life. Piaget believed that infants and toddlers “think” with their eyes, ears, hands, and other sensorimotor equipment. They cannot yet carry out many activities inside their heads. But by the end of toddlerhood, children can solve everyday practical problems and represent their experiences in speech, gesture, and play. To appreciate Piaget's view of how these vast changes take place, let's consider some important concepts.

### Piaget's Ideas About Cognitive Change

According to Piaget, specific psychological structures—organized ways of making sense of experience called **schemes**—change with age. At first, schemes are sensorimotor action patterns. For example, at 6 months, Timmy dropped objects in a fairly rigid way, simply letting go of a rattle or teething ring and watching with interest. By 18 months, his “dropping scheme” had become deliberate and creative. In tossing objects down the basement stairs, he threw some in the air, bounced others off walls, released some gently and others forcefully. Soon, instead of just acting on objects, he will show evidence of thinking before he acts. For Piaget, this change marks the transition from sensorimotor to preoperational thought.

In Piaget's theory, two processes, *adaptation* and *organization*, account for changes in schemes.

**Adaptation.** The next time you have a chance, notice how infants and toddlers tirelessly repeat actions that lead to interesting effects. **Adaptation** involves building schemes through direct interaction with the environment. It consists of two complementary activities, *assimilation* and *accommodation*. During **assimilation**, we use our current schemes to interpret the external world. For example, when Timmy dropped objects, he was assimilating them to his sensorimotor “dropping scheme.” In **accommodation**, we create new schemes or adjust old ones after

© LAURA DWIGHT PHOTOGRAPHY

In Piaget's theory, first schemes are sensorimotor action patterns. As this 12-month-old experiments with his dropping scheme, his behavior becomes more deliberate and varied.

noticing that our current ways of thinking do not capture the environment completely. When Timmy dropped objects in different ways, he modified his dropping scheme to take account of the varied properties of objects.

According to Piaget, the balance between assimilation and accommodation varies over time. When children are not changing much, they assimilate more than they accommodate—a steady, comfortable state that Piaget called cognitive *equilibrium*. During times of rapid cognitive change, children are in a state of *disequilibrium*, or cognitive discomfort. Realizing that new information does not match their current schemes, they shift from assimilation to accommodation. After modifying their schemes, they move back toward assimilation, exercising their newly changed structures until they are ready to be modified again.

Each time this back-and-forth movement between equilibrium and disequilibrium occurs, more effective schemes are produced. Because the times of greatest accommodation are the earliest ones, the sensorimotor stage is Piaget's most complex period of development.

**Organization.** Schemes also change through **organization**, a process that occurs internally, apart from direct contact with the environment. Once children form new schemes, they rearrange them, linking them with other schemes to create a strongly interconnected cognitive system. For example, eventually Timmy will relate “dropping” to “throwing” and to his developing

**TABLE 5.1**  
**Summary of Piaget's Sensorimotor Stage**

SENSORIMOTOR SUBSTAGE	TYPICAL ADAPTIVE BEHAVIORS
1. Reflexive schemes (birth–1 month)	Newborn reflexes (see Chapter 3, page 101)
2. Primary circular reactions (1–4 months)	Simple motor habits centered around the infant's own body; limited anticipation of events
3. Secondary circular reactions (4–8 months)	Actions aimed at repeating interesting effects in the surrounding world; imitation of familiar behaviors
4. Coordination of secondary circular reactions (8–12 months)	Intentional, or goal-directed, behavior; ability to find a hidden object in the first location in which it is hidden (object permanence); improved anticipation of events; imitation of behaviors slightly different from those the infant usually performs
5. Tertiary circular reactions (12–18 months)	Exploration of the properties of objects by acting on them in novel ways; imitation of novel behaviors; ability to search in several locations for a hidden object (accurate A–B search)
6. Mental representation (18 months–2 years)	Internal depictions of objects and events, as indicated by sudden solutions to problems; ability to find an object that has been moved while out of sight (invisible displacement); deferred imitation; and make-believe play

understanding of “nearness” and “farness.” According to Piaget, schemes truly reach equilibrium when they become part of a broad network of structures that can be jointly applied to the surrounding world (Piaget, 1936/1952).

In the following sections, we will first describe infant development as Piaget saw it, noting research that supports his observations. Then we will consider evidence demonstrating that in some ways, babies' cognitive competence is more advanced than Piaget believed.

## The Sensorimotor Stage

The difference between the newborn baby and the 2-year-old child is so vast that Piaget divided the sensorimotor stage into six substages, summarized in Table 5.1. Piaget based this sequence on a very small sample: his own three children. He observed his son and two daughters carefully and also presented them with everyday problems (such as hidden objects) that helped reveal their understanding of the world.

According to Piaget, at birth infants know so little that they cannot explore purposefully. The **circular reaction** provides a special means of adapting their first schemes. It involves stumbling onto a new experience caused by the baby's own motor activity. The reaction is “circular” because, as the infant tries to repeat the event again and again, a sensorimotor response that first occurred by chance strengthens into a new scheme. Consider Caitlin, who at age 2 months accidentally made a smacking sound after a feeding. Finding this new sound intriguing, she tried to repeat it until, after a few days, she became quite expert at smacking her lips.

The circular reaction initially centers on the infant's own body but later turns outward, toward manipulation of objects. In the second year, it becomes experimental and creative, aimed at producing novel outcomes. Infants' difficulty inhibiting new and interesting behaviors may underlie the circular reaction. This

immaturity in inhibition seems to be adaptive, helping to ensure that new skills will not be interrupted before they strengthen (Carey & Markman, 1999). Piaget considered revisions in the circular reaction so important that, as Table 5.1 shows, he named the sensorimotor substages after them.

**Repeating Chance Behaviors.** Piaget saw newborn reflexes as the building blocks of sensorimotor intelligence. In Substage 1, babies suck, grasp, and look in much the same way, no matter what experiences they encounter.

Around 1 month, as babies enter Substage 2, they start to gain voluntary control over their actions through the *primary circular reaction*, by repeating chance behaviors largely motivated by basic needs. This leads to some simple motor habits, such as sucking their fist or thumb. Babies in this substage also begin to vary their behavior in response to environmental demands. For

© LAURA DWIGHT PHOTOGRAPHY

When this 3-month-old accidentally hits a toy hung in front of her, she repeatedly attempts to recapture this interesting effect. In the process, she forms a new “hitting scheme.”

example, they open their mouths differently for a nipple than for a spoon. And they start to anticipate events. When hungry, 3-month-old Timmy would stop crying as soon as Vanessa entered the room—a signal that feeding time was near.

During Substage 3, from 4 to 8 months, infants sit up and reach for and manipulate objects. These motor attainments strengthen the *secondary circular reaction*, through which babies try to repeat interesting events in the surrounding environment that are caused by their own actions. For example, 4-month-old Caitlin accidentally knocked a toy hung in front of her, producing a fascinating swinging motion. Over the next three days, Caitlin tried to repeat this effect, gradually forming a new “hitting” scheme. Improved control over their own behavior permits infants to imitate others’ behavior more effectively. However, Piaget noted, they usually cannot adapt flexibly and quickly enough to imitate novel behaviors. Although they enjoy watching an adult demonstrate a game of pat-a-cake, they are not yet able to participate.

**Intentional Behavior.** In Substage 4, 8- to 12-month-olds combine schemes into new, more complex action sequences. As a result, actions that lead to new schemes no longer have a random, hit-or-miss quality—*accidentally* bringing the thumb to the mouth or *happening* to hit the toy. Instead, 8- to 12-month-olds can engage in **intentional, or goal-directed, behavior**, coordi-

© LAURA DWIGHT PHOTOGRAPHY

To find the toy hidden inside the pot, a 10-month-old engages in intentional, goal-directed behavior—the basis for all problem solving.

nating schemes deliberately to solve simple problems. Consider Piaget’s famous object-hiding task, in which he shows the baby an attractive toy and then hides it behind his hand or under a cover. Infants of this substage can find the object by coordinating two schemes—“pushing” aside the obstacle and “grasping” the toy. Piaget regarded these *means–end action sequences* as the foundation for all problem solving.

Retrieving hidden objects reveals that infants have begun to master **object permanence**, the understanding that objects continue to exist when out of sight. But this awareness is not yet complete. Babies still make the *A-not-B search error*: If they reach several times for an object at a first hiding place (A), then see it moved to a second (B), they still search for it in the first hiding place (A). Consequently, Piaget concluded that they do not have a clear image of the object as persisting when hidden from view.

Infants in Substage 4, who can better anticipate events, sometimes use their capacity for intentional behavior to try to change those events. At 10 months, Timmy crawled after Vanessa when she put on her coat, whimpering to keep her from leaving. Also, babies can now imitate behaviors slightly different from those they usually perform. After watching someone else, they try to stir with a spoon, push a toy car, or drop raisins into a cup (Piaget, 1945/1951).

In Substage 5, from 12 to 18 months, the *tertiary circular reaction*, in which toddlers repeat behaviors with variation, emerges. Recall how Timmy dropped objects over the basement steps, trying first this action, then that, then another. This deliberately exploratory approach makes 12- to 18-month-olds better problem solvers. For example, Grace figured out how to fit a shape through a hole in a container by turning and twisting it until it fell through and how to use a stick to get toys that were out of reach. According to Piaget, this capacity to experiment leads to a more advanced understanding of object permanence. Toddlers look for a hidden toy in several locations, displaying an accurate A–B search. Their more flexible action patterns also permit them to imitate many more behaviors—stacking blocks, scribbling on paper, and making funny faces.

**Mental Representation.** Substage 6 brings the ability to create **mental representations**—internal depictions of information that the mind can manipulate. Our most powerful mental representations are of two kinds: (1) *images*, or mental pictures of objects, people, and spaces; and (2) *concepts*, or categories in which similar objects or events are grouped together. We use a mental image to retrace our steps when we’ve misplaced something or to imitate someone’s behavior long after observing it. By thinking in concepts and labeling them (for example, “ball” for all rounded, movable objects used in play), we become more efficient thinkers, organizing our diverse experiences into meaningful, manageable, and memorable units.

Piaget noted that 18- to 24-month-olds arrive at solutions suddenly rather than through trial-and-error behavior. In doing so, they seem to experiment with actions inside their heads—evidence that they can mentally represent their experiences. For example, at 19 months, Grace—after bumping her new push toy

© LAURA DWIGHT PHOTOGRAPHY

The capacity for mental representation enables this 20-month-old to engage in first acts of make-believe.

against a wall—paused for a moment as if to “think,” and then immediately turned the toy in a new direction.

Representation also enables older toddlers to solve advanced object permanence problems involving *invisible displacement*—finding a toy moved while out of sight, such as into a small box while under a cover. It permits **deferred imitation**—the ability to remember and copy the behavior of models who are not present. And it makes possible **make-believe play**, in which children act out everyday and imaginary activities. As the sensorimotor stage draws to a close, mental symbols have become major instruments of thinking.

## Follow-Up Research on Infant Cognitive Development

Many studies suggest that infants display a wide array of understandings earlier than Piaget believed. Recall the operant conditioning research reviewed in Chapter 4, in which newborns sucked vigorously on a nipple to gain access to interesting sights and sounds. This behavior, which closely resembles Piaget’s secondary circular reaction, shows that infants explore and control the external world long before 4 to 8 months. In fact, they do so as soon as they are born.

To discover what infants know about hidden objects and other aspects of physical reality, researchers often use the **violation-of-expectation method**. They may *habituate* babies to

a physical event (expose them to the event until their looking declines) to familiarize them with a situation in which their knowledge will be tested. Or they may simply show babies an *expected event* (one that is consistent with reality) and an *unexpected event* (a variation of the first event that violates reality). Heightened attention to the unexpected event suggests that the infant is “surprised” by a deviation from physical reality and, therefore, is aware of that aspect of the physical world.

The violation-of-expectation method is controversial. Some researchers believe that it indicates limited, implicit (nonconscious) awareness of physical events—not the full-blown, conscious understanding that was Piaget’s focus in requiring infants to act on their surroundings, as in searching for hidden objects (Campos et al., 2008). Others maintain that the method reveals only babies’ perceptual preference for novelty, not their knowledge of the physical world (Bremner, 2010; Bremner, Slater, & Johnson, 2015). Let’s examine this debate in light of recent evidence.

**Object Permanence.** In a series of studies using the violation-of-expectation method, Renée Baillargeon and her collaborators claimed to have found evidence for object permanence in the first few months of life. Figure 5.1 describes and illustrates one of these studies, in which infants exposed to both an expected

**FIGURE 5.1** Testing young infants for understanding of object permanence using the violation-of-expectation method. (a) First, infants were habituated to two events: a short carrot and a tall carrot moving behind a yellow screen, on alternate trials. Next, the researchers presented two test events. The color of the screen was changed to help infants notice its window. (b) In the *expected event*, the carrot shorter than the window’s lower edge moved behind the blue screen and reappeared on the other side. (c) In the *unexpected event*, the carrot taller than the window’s lower edge moved behind the screen and did not appear in the window, but then emerged intact on the other side. Infants as young as 2½ to 3½ months looked longer at the *unexpected event*, suggesting that they had some understanding of object permanence. (Adapted from R. Baillargeon & J. DeVos, 1991, “Object Permanence in Young Infants: Further Evidence,” *Child Development*, 62, p. 1230. © 1991, John Wiley and Sons. Reproduced with permission of John Wiley & Sons Ltd. conveyed through Copyright Clearance Center, Inc.)

and an unexpected object-hiding event looked longer at the unexpected event (Aguiar & Baillargeon, 2002; Baillargeon & DeVos, 1991).

Additional violation-of-expectation studies yielded similar results, suggesting that infants look longer at a wide variety of unexpected events involving hidden objects (Newcombe, Sluzenski, & Huttenlocher, 2005; Wang, Baillargeon, & Paterson, 2005). Still, as previously noted, critics question what these looking preferences tell us about babies' actual understandings.

But another type of looking behavior suggests that young infants are aware that objects persist when out of view. Four- and 5-month-olds will track a ball's path of movement as it disappears and reappears from behind a barrier, even gazing ahead to where they expect it to emerge. As further support for such awareness, 5- to 9-month-olds more often engaged in such predictive tracking when a ball viewed on a computer screen gradually rolled behind a barrier than when it disappeared instantaneously or imploded (rapidly decreased in size) at the barrier's edge (Bertenthal, Gredebäck, & Boyer, 2013; Bertenthal, Longo, & Kenny, 2007). With age, babies are more likely to fixate on the predicted place of the ball's reappearance and wait for it—evidence of an increasingly secure grasp of object permanence.

If young infants do have some notion of object permanence, how do we explain Piaget's finding that even babies capable of reaching do not try to search for hidden objects before 8 months of age? Compared with looking reactions in violation-of-expectation tasks, searching for hidden objects is far more cognitively demanding: The baby must figure out where the hidden object is. Consistent with this idea, infants solve some object-hiding tasks before others. For example, 8- to 10-month-olds remove the cover from a partially hidden object before they do from a fully covered object (Moore & Meltzoff, 2008). Experience with partially hidden objects—common in infants' everyday lives—may help them grasp that a completely covered object has not been replaced by the cloth but, rather, continues to exist and can be retrieved.

Once 8- to 12-month-olds search for hidden objects, they make the A-not-B search error. Some studies suggests that they search at A (where they found the object on several previous reaches) instead of B (its most recent location) because they have trouble inhibiting a previously rewarded response or because they do not attend closely when the hiding place moves from A to B (Diamond, Cruttenden, & Neiderman, 1994; Ruffman & Langman, 2002). A more comprehensive explanation is that a complex, dynamic system of factors—having built a habit of reaching toward A, continuing to look at A, having the hiding place at B appear similar to the one at A, and maintaining a constant body posture—increases the chances that the baby will make the A-not-B search error. Disrupting any one of these factors increases 10-month-olds' accurate searching at B (Thelen et al., 2001). In addition, older infants are still perfecting reaching and grasping (see Chapter 3) (Berger, 2010). If these motor skills are challenging, babies have little attention left to focus on inhibiting their habitual reach toward A.

## LOOK and LISTEN

Using an attractive toy and cloth, try several object-hiding tasks with 8- to 14-month-olds. Is their searching behavior consistent with research findings?

In sum, mastery of object permanence is a gradual achievement. Babies' understanding becomes increasingly complex with age: They must distinguish the object from the barrier concealing it, keep track of the object's whereabouts, and use this knowledge to obtain the object (Moore & Meltzoff, 2008). Success at object search tasks coincides with rapid development of the frontal lobes of the cerebral cortex (Bell, 1998). Also crucial are a wide variety of experiences perceiving, acting on, and remembering objects.

**Mental Representation.** In Piaget's theory, before about 18 months of age, infants are unable to mentally represent experience. Yet 8- to 10-month-olds' ability to recall the location of hidden objects after delays of more than a minute, and 14-month-olds' recall after delays of a day or more, indicate that babies construct mental representations of objects and their whereabouts (McDonough, 1999; Moore & Meltzoff, 2004). And in studies of deferred imitation and problem solving, representational thought is evident even earlier.

**Deferred and Inferred Imitation.** Piaget studied imitation by noting when his three children demonstrated it in their everyday behavior. Under these conditions, a great deal must be known about the infant's daily life to be sure that deferred imitation—which requires infants to represent a model's past behavior—has occurred.

Laboratory research suggests that deferred imitation is present at 6 weeks of age! Infants who watched an unfamiliar adult's facial expression imitated it when exposed to the same adult the next day (Meltzoff & Moore, 1994). As motor capacities improve, infants copy actions with objects. In one study, an adult showed 6- and 9-month-olds a novel series of actions with a puppet: taking its glove off, shaking the glove to ring a bell inside, and replacing the glove. When tested a day later, infants who had seen the novel actions were far more likely to imitate them (see Figure 5.2). And when researchers paired a second, motionless puppet with the first puppet 1 to 6 days before the demonstration, 6- to 9-month-olds generalized the novel actions to this new, very different-looking puppet (Barr, Marrott, & Rovee-Collier, 2003; Giles & Rovee-Collier, 2011).

Between 12 and 18 months, toddlers use deferred imitation skillfully to enrich their range of sensorimotor schemes. They retain modeled behaviors for at least several months, copy the actions of peers as well as adults, and imitate across a change in context—for example, enact at home a behavior seen at child care (Meltzoff & Williamson, 2010; Patel, Gaylord, & Fagen, 2013). The ability to recall modeled behaviors in the order they occurred—evident as early as 6 months—also strengthens over

**FIGURE 5.2** Testing infants for deferred imitation. After researchers performed a novel series of actions with a puppet, this 6-month-old imitated the actions a day later: (a) removing the glove; (b) shaking the glove to ring a bell inside. With age, gains in recall are evident in deferred imitation of others' behaviors over longer delays.

BY PERMISSION OF GEORGE H. COLLIER ESTATE

the second year (Bauer, 2006; Rovee-Collier & Cuevas, 2009). And when toddlers imitate in correct sequence, they remember more behaviors (Knopf, Kraus, & Kressley-Mba, 2006).

Older infants and toddlers even imitate rationally, by *inferring* others' intentions! They are more likely to imitate purposeful rather than accidental or arbitrary behaviors on objects (Hamlin, Hallinan, & Woodward, 2008; Thoermer et al., 2013). And they adapt their imitative acts to a model's goals. If 12-month-olds see an adult perform an unusual action for fun (make a toy dog enter a miniature house by jumping through the chimney, even though its door is wide open), they copy the behavior. But if the adult engages in the odd behavior because she *must* (makes the dog go through the chimney after first trying the door and finding it locked), 12-month-olds typically imitate the more efficient action (putting the dog through the door) (Schwier et al., 2006).

Between 14 and 18 months, toddlers become increasingly adept at imitating actions an adult *tries* to produce, even if these are not fully realized (Bellagamba, Camaioni, & Colonesi, 2006; Olineck & Poulin-Dubois, 2009). On one occasion, Ginette attempted to pour some raisins into a bag but missed, spilling them onto the counter. A moment later, Grace began dropping the raisins into the bag, indicating that she had inferred Ginette's goal.

**Problem Solving.** As Piaget indicated, around 7 to 8 months, infants develop intentional means–end action sequences that they use to solve simple problems, such as pulling on a cloth to obtain a toy resting on its far end (Willatts, 1999). Out of these explorations of object-to-object relations, the capacity for tool

use in problem solving—flexibly manipulating an object as a means to a goal—emerges (Keen, 2011).

For example, 12-month-olds who were repeatedly presented with a spoon oriented so its handle pointed toward their preferred hand (usually the right) adapted their preferred-hand grip when the spoon's handle was presented in the opposite orientation (to the left). As a result, they succeeded in transporting food to their mouths most of the time (McCarty & Keen, 2005). With age, babies increasingly adjusted their grip to fit the spoon's orientation in advance, planning ahead for what they wanted to do with the tool.

By 10 to 12 months, infants can *solve problems by analogy*—apply a solution strategy from one problem to other relevant problems. In one study, babies of this age were given three similar problems, each requiring them to overcome a barrier, grasp a string, and pull it to get an attractive toy. The problems differed in many aspects of their superficial features—texture and color of the string, barrier, and floor mat and type of toy (horse, doll, or car). For the first problem, the parent demonstrated the solution and encouraged the infant to imitate (Chen, Sanchez, & Campbell, 1997). Babies obtained the toy more readily with each additional problem.

These findings suggest that at the end of the first year, infants form flexible mental representations of how to use tools to get objects. They have some ability to move beyond trial-and-error experimentation, represent a solution mentally, and use it in new contexts.

**Symbolic Understanding.** One of the most momentous early attainments is the realization that words can be used to cue

mental images of things not physically present—a symbolic capacity called **displaced reference** that emerges around the first birthday. It greatly enhances toddlers’ capacity to learn about the world through communicating with others. Observations of 12- to 13-month-olds reveal that they respond to the label of an absent toy by looking at and gesturing toward the spot where it usually rests (Saylor, 2004). As memory and vocabulary improve, skill at displaced reference expands.

But at first, toddlers have difficulty using language to acquire new information about an absent object—an ability that is essential to learn from symbols. In one study, an adult taught 19- and 22-month-olds a name for a stuffed animal—“Lucy” for a frog. Then, with the frog out of sight, each toddler was told that some water had spilled, so “Lucy’s all wet!” Finally, the adult showed the toddler three stuffed animals—a wet frog, a dry frog, and a pig—and said, “Get Lucy!” (Ganea et al., 2007). Although all the children remembered that Lucy was a frog, only the 22-month-olds identified the wet frog as Lucy. This capacity to use language as a flexible symbolic tool—to modify and enrich existing mental representations—improves from the end of the second into the third year.

A beginning awareness of the symbolic function of pictures also emerges in the first year, strengthening in the second. Even

newborns perceive a relation between a picture and its referent, as indicated by their preference for looking at a photo of their mother’s face (see page 143 in Chapter 4). By 9 months and perhaps before, the majority of infants recognize that real objects can be grasped while pictures of objects cannot. Most touch, rub, or pat a color photo of an object but rarely try to grasp it (Ziemer, Plumert, & Pick, 2012). These behaviors suggest that 9-month-olds do not mistake a picture for the real thing, though they may not yet comprehend it as a symbol. Manual exploration of pictures declines after 9 months, becoming rare around 18 months (DeLoache & Ganea, 2009).

Around this time, toddlers clearly treat pictures symbolically, as long as pictures strongly resemble real objects. After hearing a novel label (“blicket”) applied to a color photo of an unfamiliar object, most 15- to 24-month-olds—when presented with both the real object and its picture and asked to indicate the “blicket”—gave a symbolic response (Ganea et al., 2009). They selected either the real object or both the object and its picture, not the picture alone.

By the middle of the second year, toddlers often use pictures as vehicles for communicating with others and acquiring new knowledge. They point to, name, and talk about pictures, and they can apply something learned from a book with realistic-looking pictures to real objects, and vice versa (Ganea, Ma, & DeLoache, 2011; Simcock, Garrity, & Barr, 2011).

Picture-rich environments in which caregivers often direct babies’ attention to the link between pictures and real objects promote pictorial understanding. In a study carried out in a village community in Tanzania, Africa, where children receive no exposure to pictures before school entry, an adult taught 1½-year-olds a new name for an unfamiliar object during picture-book interaction (Walker, Walker, & Ganea, 2012). When later asked to pick the named object from a set of real objects, not until 3 years of age did the Tanzanian children perform as well as U.S. 15-month-olds.

Even after coming to appreciate the symbolic nature of pictures, young children have difficulty grasping the meaning of some pictures (such as line drawings), as we will see in Chapter 8. How do infants and toddlers interpret another ever-present, pictorial medium—video? See the Social Issues: Education box on the following page to find out.

## Evaluation of the Sensorimotor Stage

Table 5.2 on page 158 summarizes the remarkable cognitive attainments we have just considered. Compare this table with Piaget’s description of the sensorimotor substages in Table 5.1 on page 151. You will see that infants anticipate events, actively search for hidden objects, master the A–B object search, flexibly vary their sensorimotor schemes, engage in make-believe play, and treat pictures and video images symbolically within Piaget’s time frame. Yet other capacities—including secondary circular reactions, understanding of object properties, first signs of object permanence, deferred imitation, problem solving by analogy,

A 17-month-old points to a picture in a book, revealing her beginning awareness of the symbolic function of pictures. But pictures must be highly realistic for toddlers to treat them symbolically.

## Social Issues: Education

### Baby Learning from TV and Video: The Video Deficit Effect

Children first become TV and video viewers in early infancy, as they are exposed to programs watched by parents and older siblings or to shows aimed at viewers not yet out of diapers, such as the Baby Einstein products. U.S. parents report that 50 percent of 2-month-olds watch TV, a figure that rises to 90 percent by 2 years of age. Average viewing time increases from 55 minutes per day at 6 months to just under 1½ hours per day at age 2 (Anand et al., 2014; Cespedes et al., 2014). Although parents assume that babies learn from TV and videos, research indicates that babies cannot take full advantage of them.

Initially, infants respond to videos of people as if viewing people directly—smiling, moving their arms and legs, and (by 6 months) imitating actions of a televised adult (Barr, Muentener, & Garcia, 2007). But when shown videos of attractive toys, 9-month-olds touch and grab at the screen, suggesting that they confuse the images with the real thing. By the middle of the second year, manual exploration declines in favor of pointing at the images (Pierroutsakos & Troseth, 2003). Nevertheless, toddlers have difficulty applying what they see on video to real situations.

In a series of studies, some 2-year-olds watched through a window while a live adult hid an object in an adjoining room, while others watched the same event on a video screen. Children in the direct viewing condition retrieved the toy easily; those in the video condition had difficulty (Troseth, 2003; Troseth & DeLoache, 1998). This **video deficit effect**—poorer performance after viewing a video than a live demonstration—has also

been found for 2-year-olds' deferred imitation, word learning, and means-end problem solving (Bellagamba et al., 2012; Hayne, Herbert, & Simcock, 2003; Krcmar, Grela, & Linn, 2007).

One explanation is that 2-year-olds typically do not view a video character as offering socially relevant information. After an adult on video announced where she had hidden a toy, few 2-year-olds searched (Schmidt, Crawley-Davis, & Anderson, 2007). In contrast, when the adult uttered the same words while standing in front of the child, 2-year-olds promptly retrieved the object.

Toddlers seem to discount information on video as relevant to their everyday experiences because people do not look at and converse with them directly or establish a shared focus on objects, as their caregivers do. In one study, researchers gave some 2-year-olds an interactive video experience (using a two-way, closed-circuit video system). An adult on video interacted with the child for five minutes—calling the child by name, talking about the child's siblings and pets, waiting for the child to respond, and playing interactive games (Troseth, Saylor, & Archer, 2006). Compared with 2-year-olds who viewed the same adult in a noninteractive video, those in the interactive condition were far more successful in

A 2-year-old looks puzzled by a video image. Perhaps she has difficulty grasping its meaning because onscreen characters do not converse with her directly, as adults in real life do.

using a verbal cue from a person on video to retrieve a toy.

Around age 2½, the video deficit effect declines. Before this age, the American Academy of Pediatrics (2001) recommends against mass media exposure. In support of this advice, amount of TV viewing is negatively related to toddlers' language progress (Zimmerman, Christakis, & Meltzoff, 2007). And 1- to 3-year-old heavy viewers tend to have attention, memory, and reading difficulties in the early school years (Christakis et al., 2004; Zimmerman & Christakis, 2005).

When toddlers do watch TV and video, it is likely to work best as a teaching tool when it is rich in social cues (Lauricella, Gola, & Calvert, 2011). These include use of familiar characters and close-ups in which the character looks directly at the camera, addresses questions to viewers, and pauses to invite a response.

and displaced reference of words—emerge earlier than Piaget expected. These findings show that the cognitive attainments of infancy and toddlerhood do not develop together in the neat, stepwise fashion that Piaget assumed.

Recent research raises questions about Piaget's view of how infant development takes place. Consistent with Piaget's ideas, sensorimotor action helps infants construct some forms of

knowledge. For example, as we saw in Chapter 4, crawling enhances depth perception and ability to find hidden objects, and manipulating objects fosters awareness of object properties. Yet we have also seen that infants comprehend a great deal before they are capable of the motor behaviors that Piaget assumed led to those understandings. How can we account for babies' amazing cognitive accomplishments?

**TABLE 5.2**  
**Some Cognitive Attainments of Infancy and Toddlerhood**

AGE	COGNITIVE ATTAINMENTS
Birth–1 month	Secondary circular reactions using limited motor skills, such as sucking a nipple to gain access to interesting sights and sounds
1–4 months	Awareness of object permanence, object solidity, and gravity, as suggested by violation-of-expectation findings; deferred imitation of an adult’s facial expression over a short delay (1 day)
4–8 months	Improved knowledge of object properties and basic numerical knowledge, as suggested by violation-of-expectation findings; deferred imitation of an adult’s novel actions on objects over a short delay (1 to 3 days)
8–12 months	Ability to search for a hidden object; ability to solve simple problems by analogy to a previous problem
12–18 months	Ability to search for a hidden object when it is moved from one location to another (accurate A–B search); deferred imitation of an adult’s novel actions on objects after long delays (at least several months) and across a change in situation (from child care to home); rational imitation, inferring the model’s intentions; displaced reference of words
18 months–2 years	Ability to find an object moved while out of sight (invisible displacement); deferred imitation of actions an adult tries to produce, even if these are not fully realized; deferred imitation of everyday behaviors in make-believe play; beginning awareness of pictures and video as symbols of reality

**Alternative Explanations.** Unlike Piaget, who thought young babies constructed all mental representations out of sensorimotor activity, most researchers now believe that infants have some built-in cognitive equipment for making sense of experience. But intense disagreement exists over the extent of this initial understanding. As we have seen, much evidence on young infants’ cognition rests on the violation-of-expectation method. Researchers who lack confidence in this method argue that babies’ cognitive starting point is limited (Bremner, Slater, & Johnson, 2015; Cohen, 2010; Kagan, 2013c). For example, some believe that newborns begin life with a set of biases for attending to certain information and with general-purpose learning procedures—such as powerful techniques for analyzing complex perceptual information (Bahrick, 2010; MacWhinney, 2015; Rakison, 2010). Together, these capacities enable infants to construct a wide variety of schemes.

Others, convinced by violation-of-expectation findings, believe that infants start out with impressive understandings. According to this **core knowledge perspective**, babies are born with a set of innate knowledge systems, or *core domains of thought*. Each of these prewired understandings permits a ready grasp of new, related information and therefore supports early, rapid development (Carey, 2009; Leslie, 2004; Spelke & Kinzler, 2007, 2013). Core knowledge theorists argue that infants could not make sense of the complex stimulation around them without having been genetically “set up” in the course of evolution to comprehend its crucial aspects.

Researchers have conducted many studies of infants’ *physical knowledge*, including object permanence, object solidity (that one object cannot move through another), and gravity (that an object will fall without support). Violation-of-expectation findings suggest that in the first few months, infants have some awareness of all these basic object properties and quickly build on this knowledge (Baillargeon et al., 2009, 2011). Core knowl-

edge theorists also assume that an inherited foundation of *linguistic knowledge* enables swift language acquisition in early childhood—a possibility we will consider later in this chapter. Furthermore, these theorists argue, infants’ early orientation toward people initiates rapid development of *psychological knowledge*—in particular, understanding of mental states, such as intentions, emotions, desires, and beliefs, which we will address further in Chapter 6.

Research even suggests that infants have basic *numerical knowledge*. In the best-known study, 5-month-olds saw a screen raised to hide a single toy animal and then watched a hand place a second toy behind the screen. Finally, the screen was removed to reveal either one or two toys. If infants kept track of the two objects (requiring them to add one object to another), then they should look longer at the unexpected, one-toy display—which is what they did (see Figure 5.3) (Wynn, 1992). These findings and others suggest that babies can discriminate quantities up to three and use that knowledge to perform simple arithmetic—both addition and subtraction (in which two objects are covered and one object is removed) (Kobayashi, Hiraki, & Hasegawa, 2005; Walden et al., 2007; Wynn, Bloom, & Chiang, 2002).

Additional evidence suggests that 6-month-olds can distinguish among large sets of items, as long as the difference between those sets is very great—at least a factor of two. For example, they can tell the difference between 8 and 16 dots but not between 8 and 12 (Lipton & Spelke, 2003; Xu, Spelke, & Goddard, 2005). Consequently, some researchers believe that infants can represent approximate large-number values in addition to the small-number discriminations evident in Figure 5.3.

As with other violation-of-expectation results, this evidence is controversial. Skeptics question whether other aspects of object displays, rather than numerical sensitivity, are responsible for the findings (Clearfield & Westfahl, 2006; Langer, Gillette, & Arriaga, 2003). Furthermore, indisputable evidence for

**FIGURE 5.3 Testing infants for basic number concepts.** (a) First, infants saw a screen raised in front of a toy animal. Then an identical toy was added behind the screen. Next, the researchers presented two outcomes. (b) In the *expected outcome*, the screen dropped to reveal two toy animals. (c) In the *unexpected outcome*, the screen dropped to reveal one toy animal. Five-month-olds shown the unexpected outcome looked longer than did 5-month-olds shown the expected outcome. The researchers concluded that infants can discriminate the quantities “one” and “two” and use that knowledge to perform simple addition:  $1 + 1 = 2$ . A variation of this procedure suggested that 5-month-olds could also do simple subtraction:  $2 - 1 = 1$ . (From K. Wynn, 1992, “Addition and Subtraction by Human Infants.” *Nature*, 358, p. 749. © 1992 by Nature Publishing Group. Adapted with permission of Nature Publishing Group in the format “Republish in a book” via Copyright Clearance Center.)

built-in core knowledge requires that it be demonstrated at birth or close to it—in the absence of relevant opportunities to learn. Yet evidence on newborns’ ability to process small and large numerical values is inconsistent (Coubart et al., 2014; Izard et al., 2009). And critics point out that claims for infants’ number knowledge are surprising, in view of other research indicating that before 14 to 16 months, toddlers have difficulty making less-than and greater-than comparisons between small sets. Not until the preschool years do children add and subtract small sets correctly.

The core knowledge perspective, while emphasizing native endowment, acknowledges that experience is essential for children to extend this initial knowledge. But so far, it has said little about which experiences are most important in each core domain and how those experiences advance children’s thinking. Despite challenges, core knowledge investigators have sharpened the field’s focus on clarifying the starting point for human cognition and on carefully tracking the changes that build on it.

**Piaget’s Legacy.** Follow-up research on Piaget’s sensorimotor stage yields broad agreement on two issues. First, many cognitive changes of infancy are gradual and continuous rather than abrupt and stagelike, as Piaget thought (Bjorklund, 2012). Second, rather than developing together, various aspects of infant cognition change unevenly because of the challenges posed by different types of tasks and infants’ varying experiences with

them. These ideas serve as the basis for another major approach to cognitive development—*information processing*.

Before we turn to this alternative point of view, let’s recognize Piaget’s enormous contributions. Piaget’s work inspired a wealth of research on infant cognition, including studies that challenged his theory. Today, researchers are far from consensus on how to modify or replace his account of infant cognitive development, and some believe that his general approach continues to make sense and fits considerable evidence (Cohen, 2010). Piaget’s observations also have been of great practical value. Teachers and caregivers continue to look to the sensorimotor stage for guidelines on how to create developmentally appropriate environments for infants and toddlers.

## Ask yourself

**CONNECT** Which of the capacities listed in Table 5.2 indicate that mental representation emerges earlier than Piaget believed?

**APPLY** Several times, after her father hid a teething biscuit under a red cup, 12-month-old Mimi retrieved it easily. Then Mimi’s father hid the biscuit under a nearby yellow cup. Why did Mimi persist in searching for it under the red cup?

**REFLECT** What advice would you give the typical U.S. parent about permitting an infant or toddler to watch as much as 1 to 1½ hours of TV or video per day? Explain.

## Information Processing

**5.4** Describe the information-processing view of cognitive development and the general structure of the information-processing system.

**5.5** What changes in attention, memory, and categorization take place over the first two years?

**5.6** Describe the strengths and limitations of the information-processing approach to early cognitive development.

Information-processing researchers agree with Piaget that children are active, inquiring beings. But instead of providing a single, unified theory of cognitive development, they focus on many aspects of thinking, from attention, memory, and categorization skills to complex problem solving.

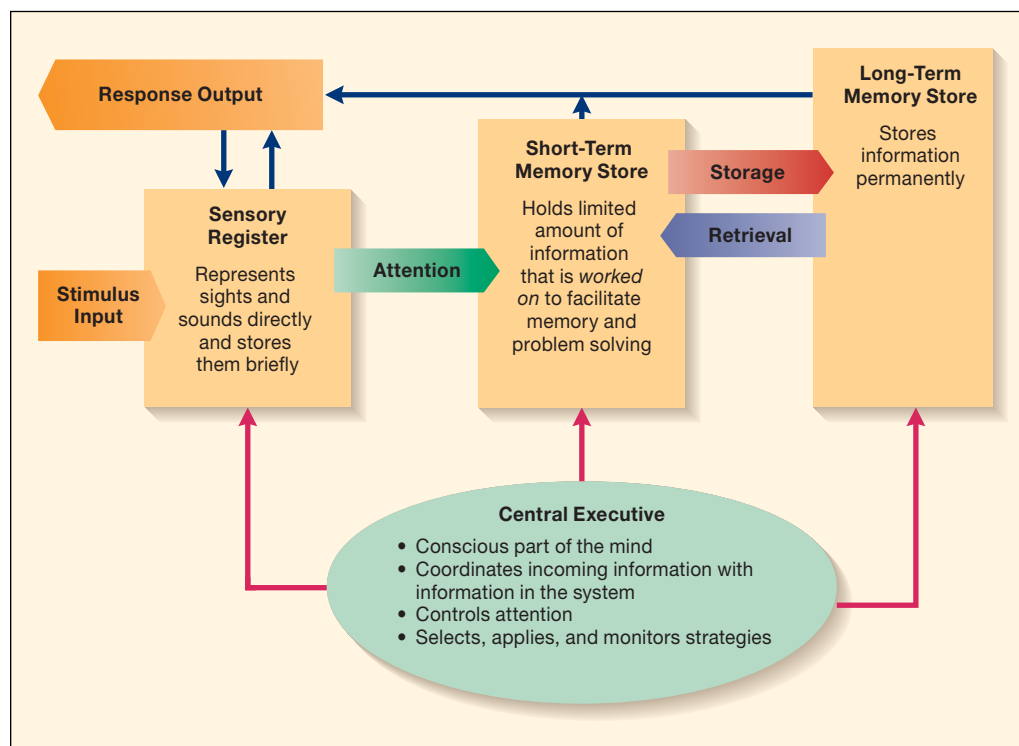

Recall from Chapter 1 that the information-processing approach frequently relies on computer-like flowcharts to describe the human cognitive system. Information-processing theorists are not satisfied with general concepts, such as assimilation and accommodation, to describe how children think. Instead, they want to know exactly what individuals of different ages do when faced with a task or problem (Birney & Sternberg, 2011). The computer model of human thinking is attractive because it is explicit and precise.

## A General Model of Information Processing

Most information-processing researchers assume that we hold information in three parts of the mental system for processing: the *sensory register*, the *short-term memory store*, and the *long-term memory store* (see Figure 5.4). As information flows through each, we can use *mental strategies* to operate on and transform it, increasing the chances that we will retain information, use it efficiently, and think flexibly, adapting it to changing circumstances. To understand this more clearly, let's look at each aspect of the mental system.

First, information enters the **sensory register**, where sights and sounds are represented directly and stored briefly. Look around you, and then close your eyes. An image of what you saw persists momentarily, but then it decays, or disappears, unless you use mental strategies to preserve it. For example, by *attending* to some information more carefully than to other information, you increase the chances that it will transfer to the next step of the information-processing system.

In the second part of the mind, the **short-term memory store**, we retain attended-to information briefly so we can actively “work on” it to reach our goals. One way of looking at the short-term store is in terms of its *basic capacity*, often

**FIGURE 5.4 Model of the human information-processing system.** Information flows through three parts of the mental system: the *sensory register*, the *short-term memory store*, and the *long-term memory store*. In each, mental strategies can be used to manipulate information, increasing the efficiency and flexibility of thinking and the chances that information will be retained. The *central executive* is the conscious, reflective part of the mental system. It coordinates incoming information with information already in the system, decides what to attend to, and oversees the use of strategies.

referred to as *short-term memory*: how many pieces of information can be held at once for a few seconds. But most researchers endorse a contemporary view of the short-term store, which offers a more meaningful indicator of its capacity, called **working memory**—the number of items that can be briefly held in mind while also engaging in some effort to monitor or manipulate those items. Working memory can be thought of as a “mental workspace” that we use to accomplish many activities in daily life. From childhood on, researchers assess changes in its capacity by presenting individuals with lists of items (such as numerical digits or short sentences), asking them to work on the items (for example, repeat the digits backward or remember the final word of each sentence in correct order), and seeing how well they do.

The sensory register can take in a wide panorama of information. Short-term and working memory are far more restricted, though their capacity increases steadily from early childhood to early adulthood—on a verbatim digit-span task tapping short-term memory, from about two to seven items; and on working-memory tasks, from about two to five items (Cowan & Alloway, 2009). Still, individual differences are evident at all ages. By engaging in a variety of basic cognitive procedures, such as focusing attention on relevant items and repeating (rehearsing) them rapidly, we increase the chances that information will be retained and accessible to ongoing thinking.

To manage the cognitive system’s activities, the **central executive** directs the flow of information, implementing the basic procedures just mentioned and also engaging in more sophisticated activities that enable complex, flexible thinking. For example, the central executive coordinates incoming information with information already in the system, and it selects, applies, and monitors strategies that facilitate memory storage, comprehension, reasoning, and problem solving (Pressley & Hilden, 2006). The central executive is the conscious, reflective part of our mental system.

The more effectively the central executive joins with working memory to process information, the better learned cognitive activities will be and the more *automatically* we can apply them. Consider the richness of your thinking while you automatically drive a car. **Automatic processes** are so well-learned that they require no space in working memory and, therefore, permit us to focus on other information while performing them. Furthermore, the more effectively we process information in working memory, the more likely it will transfer to the third, and largest, storage area—**long-term memory**, our permanent knowledge base, which is unlimited. In fact, we store so much in long-term memory that *retrieval*—getting information back from the system—can be problematic. To aid retrieval, we apply strategies, just as we do in working memory. Information in long-term memory is *categorized* by its contents, much like a digital library reference system that enables us to retrieve items by following the same network of associations used to store them in the first place.

Information-processing researchers believe that several aspects of the cognitive system improve during childhood and adolescence: (1) the *basic capacity* of its stores, especially

working memory; (2) the *speed* with which information is worked on; and (3) the *functioning of the central executive*. Together, these changes make possible more complex forms of thinking with age (Halford & Andrews, 2010).

Gains in working-memory capacity are due in part to brain development, but greater processing speed also contributes. Fast, fluent thinking frees working-memory resources to support storage and manipulation of additional information. Furthermore, researchers have become increasingly interested in studying the development of **executive function**—the diverse cognitive operations and strategies that enable us to achieve our goals in cognitively challenging situations. These include controlling attention by inhibiting impulses and irrelevant information and by flexibly directing thought and behavior to suit the demands of a task; coordinating information in working memory; and planning—capacities governed by the prefrontal cortex and its elaborate connections to other brain regions (Chevalier, 2015; Müller & Kerns, 2015). The reason for investigators’ great interest is that measures of executive function in childhood predict important cognitive and social outcomes—including task persistence, self-control, academic achievement, and interpersonal acceptance—in adolescence and adulthood (Carlson, Zelazo, & Faja, 2013).

As we will see, gains in aspects of executive function are under way in the first two years. Dramatic strides will follow in childhood and adolescence.

## Attention

Recall from Chapter 4 that around 2 to 3 months of age, infants shift from focusing on single, high-contrast features to exploring objects and patterns more thoroughly—visual search behavior that improves over the first year (Frank, Amso, & Johnson, 2014). Besides attending to more aspects of the environment, infants gradually become more efficient at managing their attention, taking in information more quickly. Habituation research reveals that preterm and newborn babies require a long time—about 3 to 4 minutes—to habituate and recover to novel visual stimuli. But by 4 or 5 months, they need as little as 5 to 10 seconds to take in a complex visual stimulus and recognize it as different from a previous one (Colombo, Kapa, & Curtindale, 2011).

One reason that very young babies’ habituation times are so much longer is that they have difficulty disengaging attention from a stimulus (Colombo, 2002). When Carolyn held up a colorful rattle, 2-month-old Caitlin stared intently until, unable to break her gaze, she burst into tears. The ability to shift attention from one stimulus to another improves by 4 months—a change believed to be due to development of structures in the cerebral cortex controlling eye movements (Posner & Rothbart, 2007).

Over the first year, infants mostly attend to novel and eye-catching events. In the second year, as toddlers become increasingly capable of intentional behavior (refer back to Piaget’s Substage 4), attraction to novelty declines (but does not disappear) and *sustained attention* increases, especially when children

© LAURA DWIGHT PHOTOGRAPHY

By encouraging her toddler's goal-directed play, this mother promotes sustained attention.

play with toys. A toddler who engages even in simple goal-directed behavior, such as stacking blocks or putting them in a container, must sustain attention to reach the goal (Ruff & Capozzoli, 2003). As plans and activities gradually become more complex, the duration of attention increases.

## Memory

Methods devised to assess infants' short-term memory, which require keeping in mind an increasingly longer sequence of very briefly presented visual stimuli, reveal that retention increases from one item at age 6 months to two to four items at 12 months (Oakes, Ross-Sheehy, & Luck, 2007). Operant conditioning and habituation techniques, which grant babies more time to process information, provide windows into early long-term memory. Both methods show that retention of visual events improves greatly with age.

Using operant conditioning, researchers study infant memory by teaching 2- to 6-month-olds to move a mobile by kicking a foot tied to it with a long cord. Two-month-olds remember how to activate the mobile for 1 to 2 days after training, and 3-month-olds for one week. By 6 months, memory increases to two weeks (Rovee-Collier, 1999; Rovee-Collier & Bhatt, 1993). Around the middle of the first year, babies can manipulate switches or buttons to control stimulation. When 6- to 18-month-olds pressed a

lever to make a toy train move around a track, duration of memory continued to increase with age; 13 weeks after training, 18-month-olds still remembered how to press the lever (see Figure 5.5) (Hartshorn et al., 1998).

Even after 2- to 6-month-olds forget an operant response, they need only a brief prompt—an adult who shakes the mobile—to reinstate the memory (Hildreth & Rovee-Collier, 2002). And when 6-month-olds are given a chance to reactivate the response themselves for just a couple of minutes, their memory not only returns but extends dramatically, to about 17 weeks (Rovee-Collier & Cuevas, 2009). Perhaps permitting the baby to generate the previously learned behavior strengthens memory because it reexposes the child to more aspects of the original learning situation.

Habituation studies show that infants learn and retain a wide variety of information just by watching objects and events, without being physically active. Sometimes, their retention is much longer than in operant conditioning studies. Babies are especially captivated by the movements of objects and people. For example, 3- to 5-month-olds' retention of the unusual movements of objects (such as a metal nut swinging on the end of a string) persists for at least three months (Bahrick, Hernandez-Reif, & Pickens, 1997). By contrast, their memory for the faces of unfamiliar people and the features of objects is short-lived—only about 24 hours.

**FIGURE 5.5** Increase in retention in two operant conditioning tasks from 2 to 18 months. Two- to 6-month-olds were trained to make a kicking response that turned a mobile. Six- to 18-month-olds were trained to press a lever that made a toy train move around a track. Six-month-olds learned both responses and retained them for an identical length of time, indicating that the tasks are comparable. Consequently, researchers could plot a single line tracking gains in retention from 2 to 18 months of age. The line shows that memory improves dramatically. (From C. Rovee-Collier & R. Barr, 2001, "Infant Learning and Memory," in G. Bremner & A. Fogel [Eds.], *Blackwell Handbook of Infant Development*, Oxford, UK: Blackwell, p. 150. © 2001, 2004 by Blackwell Publishing Ltd.)

By 10 months, infants remember both novel actions and the features of objects involved in those actions equally well (Baumgartner & Oakes, 2011). This improved sensitivity to object appearance is fostered by infants' increasing ability to manipulate objects, which helps them learn about objects' observable properties.

So far, we have discussed only **recognition**—noticing when a stimulus is identical or similar to one previously experienced. It is the simplest form of memory: All babies have to do is indicate (by kicking, pressing a lever, or looking) whether a new stimulus is identical or similar to a previous one. **Recall** is more challenging because it involves remembering something not present. But by the middle of the first year, infants are capable of recall, as indicated by their ability to find hidden objects and engage in deferred imitation.

Recall, too, improves steadily with age. For example, 1-year-olds can retain short sequences of adult-modeled behaviors for up to 3 months, and 1½-year-olds can do so for as long as 12 months. The ability to recall modeled behaviors in the order in which they occurred—evident as early as 6 months—strengthens over the second year (Bauer, Larkina, & Deocampo, 2011; Rovee-Collier & Cuevas, 2009). And when toddlers imitate in correct sequence, processing relations between actions, they remember more.

Long-term recall depends on connections among multiple regions of the cerebral cortex, especially with the prefrontal cortex. Formation of these neural circuits is under way in infancy and toddlerhood and will accelerate in early childhood (Jabès & Nelson, 2014). The evidence as a whole indicates that infants' memory processing is remarkably similar to that of older children and adults: Babies have distinct short-term and long-term memories and display both recognition and recall. And they acquire information quickly and retain it over time, doing so more effectively with age (Howe, 2015). Yet a puzzling finding is that older children and adults no longer recall their earliest experiences! See the Biology and Environment box on pages 164–165 for a discussion of *infantile amnesia*.

## Categorization

Even young infants can *categorize*, grouping similar objects and events into a single representation. Categorization reduces the enormous amount of new information infants encounter every day, helping them learn and remember (Rakison, 2010).

Creative variations of operant conditioning research with mobiles have been used to investigate infant categorization. One such study, of 3-month-olds, is described and illustrated in Figure 5.6. Similar investigations reveal that in the first few months, babies categorize stimuli on the basis of shape, size, and other physical properties (Wasserman & Rovee-Collier, 2001). By 6 months of age, they can categorize on the basis of two correlated features—for example, the shape and color of an alphabet letter (Bhatt et al., 2004). This ability to categorize using clusters of features prepares babies for acquiring many complex everyday categories.

Habituation has also been used to study infant categorization. Researchers show babies a series of pictures or toys belonging to one category and then see whether they recover to (look longer at) a picture that is not a member of the category or, in the case of toys, spend more time manipulating the out-of-category item. Findings reveal that by the second half of the first year, infants group familiar objects into an impressive array of categories—food items, furniture, birds, land animals, air animals, sea animals, plants, vehicles, kitchen utensils, and spatial location (“above” and “below,” “on” and “in”) (Bornstein, Arterberry, & Mash, 2010; Casasola & Park, 2013; Sloutsky, 2015). Besides organizing the physical world, infants of this age categorize their emotional and social worlds. They sort people and their voices by gender and age, begin to distinguish emotional expressions, separate people's natural actions (walking) from other motions, and expect people (but not inanimate objects) to move spontaneously (Spelke, Phillips, & Woodward, 1995; see also Chapter 4, pages 141–143).

BY PERMISSION OF GEORGE H. COLLIER ESTATE

**FIGURE 5.6 Investigating infant categorization using operant conditioning.** Three-month-olds were taught to kick to move a mobile that was made of small blocks, all with the letter A on them. After a delay, kicking returned to a high level only if the babies were shown a mobile whose elements were labeled with the same form (the letter A). If the form was changed (from As to 2s), infants no longer kicked vigorously. While making the mobile move, the babies had grouped together its features. They associated the kicking response with the category A and, at later testing, distinguished it from the category 2. (Bhatt, Rovee-Collier, & Weiner, 1994; Hayne, Rovee-Collier, & Perris, 1987.)

## Biology and Environment

### Infantile Amnesia

If infants and toddlers recall many aspects of their everyday lives, how do we explain **infantile amnesia**—that most of us can retrieve few, if any, events that happened to us before age 2 to 3? The reason cannot be merely the passage of time because we can recall many personally meaningful one-time events from both the recent and the distant past: the day a sibling was born or a move to a new house—recollections known as **autobiographical memory**.

Several explanations of infantile amnesia exist. One theory credits brain development, pointing to the *hippocampus* (located just under the temporal lobes of the cerebral cortex), which plays a vital role in the formation of new memories. Though its overall structure is formed prenatally, the hippocampus continues to add new neurons well after birth. Integrating those neurons into existing neural circuits is believed to disrupt already stored early memories (Josselyn & Frankland, 2012). In support of this view, the decline in production of hippocampal neurons—in monkeys and rats as well as in humans—coincides with the ability to form stable, long-term memories of unique experiences.

Another conjecture is that older children and adults often use verbal means for storing information, whereas infants' and toddlers' memory processing is largely nonverbal—an incompatibility that may prevent long-term retention of early experiences. To test this idea, researchers sent two adults to the homes of 2- to 4-year-olds with an unusual toy that the children were likely to remember: the Magic Shrinking Machine, shown in Figure 5.7. One adult showed the child how, after inserting an object in an opening on top of the machine and turning a crank that activated flashing lights and musical sounds, the child could retrieve a smaller, identical object (discreetly dropped down a chute by the second adult) from behind a door on the front of the machine.

A day later, the researchers tested the children to see how well they recalled the event. Their nonverbal memory—based on acting out the “shrinking” event and recognizing the “shrunkened” objects in photos—was excellent. But even when they had the vocabulary, children younger than age 3 had trouble describing features of the “shrinking” experience. Verbal recall increased sharply

between ages 3 and 4, when infantile amnesia typically subsides (Simcock & Hayne, 2003, p. 813). In a follow-up study, which assessed verbal recall 6 years later, only 19 percent—including two children who were younger than age 3—remembered the “shrinking” event (Jack, Simcock, & Hayne, 2012). Those who recalled were more likely to have participated in conversations with a parent about the experience, which could have helped them gain verbal access to the memory.

These findings help reconcile infants' and toddlers' remarkable memory skills with infantile amnesia. During the first few years, children rely heavily on nonverbal memory techniques, such as visual images and motor actions. As language develops, their ability to use it to refer to preverbal memories requires considerable support from adults. As children encode autobiographical events in verbal form, they use language-based cues to retrieve them, increasing the accessibility of these memories at later ages (Peterson, Warren, & Short, 2011).

Other evidence indicates that the advent of a clear self-image contributes to the end

Babies' earliest categories are based on similar overall appearance or prominent object part: legs for animals, wheels for vehicles. But as infants approach their first birthday, more categories appear to be based on subtle sets of features (Cohen, 2003; Mandler, 2004; Quinn, 2008). Older infants can even make categorical distinctions when the perceptual contrast between two categories is minimal (birds versus airplanes).

As they gain experience in comparing to-be-categorized items in varied ways and as their store of verbal labels expands, toddlers start to categorize flexibly: When 14-month-olds are given four balls and four blocks, some made of soft rubber and some of rigid plastic, their sequence of object touching reveals that after classifying by shape, they can switch to classifying by material (soft versus hard) if an adult calls their attention to the new basis for grouping (Ellis & Oakes, 2006).

In addition to touching and sorting, toddlers' categorization skills are evident in their play behaviors. After watching an adult give a toy dog a drink from a cup, most 14-month-olds shown a

rabbit and a motorcycle offered the drink only to the rabbit (Mandler & McDonough, 1998). They clearly understood that certain actions are appropriate for some categories of items (animals) but not for others (vehicles).

By the end of the second year, toddlers' grasp of the animate–inanimate distinction expands. Nonlinear motions are typical of animates (a person or a dog jumping), linear motions of inanimates (a car or a table pushed along a surface). At 18 months, toddlers more often imitate a nonlinear motion with a toy that has animate-like parts (legs), even if it represents an inanimate (a bed). At 22 months, displaying a fuller understanding, they imitate a nonlinear motion only with toys in the animate category (a cat but not a bed) (Rakison, 2005). They seem to realize that whereas animates are self-propelled and therefore have varied paths of movement, inanimates move only when acted on, in highly restricted ways.

Researchers disagree on how toddlers gradually shift from categorizing on the basis of prominent perceptual features

**FIGURE 5.7** The Magic Shrinking Machine, used to test young children’s verbal and nonverbal memory of an unusual event. After being shown how the machine worked, the child participated in selecting objects from a polka-dot bag, dropping them into the top of the machine (a), and turning a crank, which produced a “shrunk” object (b). When tested the next day, 2- to 4-year-olds’ nonverbal memory for the event was excellent. But below 36 months, verbal recall was poor, based on the number of features recalled about the game during an open-ended interview (c). Recall improved between 36 and 48 months. (From G. Simcock & H. Hayne, 2003, “Age-Related Changes in Verbal and Nonverbal Memory During Early Childhood,” *Developmental Psychology*, 39, pp. 807, 809. Copyright © 2003 by the American Psychological Association. Photos: Ross Coombes/Courtesy of Harlene Hayne.)

of infantile amnesia. For example, among children and adolescents, average age of earliest memory is around age 2 to 2½ (Howe, 2014; Tustin & Hayne, 2010). Though these recollections are sparse in information recalled, their timing coincides with the age at which toddlers display firmer self-

awareness, reflected in pointing to themselves in photos and referring to themselves by name.

Very likely, both neurobiological change and social experience contribute to the decline of infantile amnesia. Brain development and adult–child interaction may jointly foster

self-awareness, language, and improved memory, which enable children to talk with adults about significant past experiences (Howe, 2015). As a result, preschoolers begin to construct a long-lasting autobiographical narrative of their lives and enter into the history of their family and community.

(objects with flapping wings and feathers belong to one category; objects with rigid wings and a smooth surface to another) to categorizing on a conceptual basis, grouping objects by their common function or behavior (birds versus airplanes, dogs versus cats) (Madole, Oakes, & Rakison, 2011; Mandler, 2004; Träuble & Pauen, 2011). But all acknowledge that exploration of objects and expanding knowledge of the world contribute. In addition, adult labeling of a set of objects with a consistently applied word—“Look at the car!” “Do you see the car?”—calls babies’ attention to commonalities among objects, fostering categorization as early as 3 to 4 months of age (Ferry, Hespos, & Waxman, 2010). Toddlers’ vocabulary growth, in turn, promotes categorization by highlighting new categorical distinctions (Cohen & Brunt, 2009).

By age 2, toddlers can use conceptual similarity to guide behavior in increasingly novel situations, which greatly enhances the flexibility of their analogical problem solving. In one study, 24-month-olds watched as an adult constructed a toy animal

resembling a monkey using wooden, Velcro, and plastic pieces and then labeled it a “thornby.” A day later, the toddlers were given a different set of wooden, Velcro, and plastic materials that, when put together, resembled a rabbit (Hayne & Gross, 2015). Those asked to make a “thornby” out of “these other things” readily formed a category and applied the adult’s actions with the first animal to constructing the second, novel animal. A control group not presented with verbal cues performed poorly.

Variations among languages lead to cultural differences in development of categories. Korean toddlers, who learn a language in which object names are often omitted from sentences, develop object-sorting skills later than their English-speaking counterparts (Gopnik & Choi, 1990). At the same time, Korean contains a common word, *kkita*, with no English equivalent, referring to a tight fit between objects in contact (a ring on a finger, a cap on a pen), so Korean toddlers are advanced in forming the spatial category “tight fit” (Choi et al., 1999).

## Evaluation of Information-Processing Findings

The information-processing perspective underscores the continuity of human thinking from infancy into adult life. In attending to the environment, remembering everyday events, and categorizing objects, Caitlin, Grace, and Timmy think in ways that are remarkably similar to our own, though their mental processing is far from proficient. Findings on memory and categorization join with other research in challenging Piaget's view of early cognitive development. Infants' capacity to recall events and to categorize stimuli attests, once again, to their ability to mentally represent their experiences.

Information-processing research has contributed greatly to our view of infants and toddlers as sophisticated cognitive beings. But its central strength—analyzing cognition into its components, such as perception, attention, memory, and categorization—is also its greatest drawback: Information processing has had difficulty putting these components back together into a broad, comprehensive theory.

One approach to overcoming this weakness has been to combine Piaget's theory with the information-processing approach, an effort we will explore in Chapter 9. A more recent trend has been the application of a *dynamic systems view* (see Chapter 4, pages 135–136) to early cognition. In this approach, researchers analyze each cognitive attainment to see how it results from a complex system of prior accomplishments and the child's current goals (Spencer, Perone, & Buss, 2011; Thelen & Smith, 2006). Once these ideas are fully tested, they may move the field closer to a more powerful view of how the minds of infants and children develop.

## The Social Context of Early Cognitive Development

**5.7** How does Vygotsky's concept of the zone of proximal development expand our understanding of early cognitive development?

Recall the description at the beginning of this chapter of Grace dropping shapes into a container. Notice that she learns about the toy with Ginette's help. With adult support, Grace will gradually become better at matching shapes to openings and dropping them into the container. Then she will be able to perform this and similar activities on her own.

Vygotsky's sociocultural theory emphasizes that children live in rich social and cultural contexts that affect the way their cognitive world is structured (Bodrova & Leong, 2007; Rogoff, 2003). Vygotsky believed that complex mental activities have their origins in social interaction. Through joint activities with more mature members of their society, children master activities and think in ways that have meaning in their culture.

© JAMES SHAFFER/PHOTODISC

By bringing the task within his son's zone of proximal development and adjusting his communication to suit the child's needs, this father transfers mental strategies to the child, promoting his cognitive development.

A special Vygotskian concept explains how this happens. The **zone of proximal** (or potential) **development** refers to a range of tasks that the child cannot yet handle alone but can do with the help of more skilled partners. To understand this idea, think about how a sensitive adult (such as Ginette) introduces a child to a new activity. The adult picks a task that the child can master but that is challenging enough that the child cannot do it by herself. As the adult guides and supports, the child joins in the interaction and picks up mental strategies. As her competence increases, the adult steps back, permitting the child to take more responsibility for the task. This form of teaching—known as *scaffolding*—promotes learning at all ages, and we will consider it further in Chapter 7.

Vygotsky's ideas have been applied mostly to preschool and school-age children, who are more skilled in language and social communication. Recently, however, his theory has been extended to infancy and toddlerhood. Recall that babies are equipped with capabilities that ensure that caregivers will interact with them (Csibra & Gergely, 2011). Then adults adjust the task and their communication to the child's current level of performance in ways that promote learning.

Consider an adult helping a baby figure out how a jack-in-the-box works. In the early months, the adult demonstrates and, as the clown pops out, tries to capture the infant's attention by saying something like "See what happened!" By the end of the first year, when cognitive and motor skills have improved, the adult guides the baby's hand in turning the crank. During the

second year, the adult helps from a distance using gestures and verbal prompts, such as pointing to the crank, making a turning motion, and verbally prompting, “Turn it!” This fine-tuned support is related to advanced play, language, and problem solving in toddlerhood and early childhood (Bornstein et al., 1992; Charman et al., 2001; Tamis-LeMonda & Bornstein, 1989).

As early as the first year, cultural variations in social experiences affect mental strategies. In the jack-in-the-box example, adults and children focus on a single activity. This strategy, common in Western middle-SES homes, is well-suited to lessons in which children master skills apart from the everyday situations in which they will later use those skills. In contrast, infants and young children in Guatemalan Mayan, Native American, and other indigenous communities often attend to several events at once. For example, one 12-month-old skillfully put objects in a jar while watching a passing truck and blowing into a toy whistle (Chavajay & Rogoff, 1999; Correa-Chávez, Roberts, & Perez, 2011).

Processing several competing events simultaneously may be vital in cultures where children largely learn through keen observation of others’ ongoing activities. In a comparison of 18-month-olds from German middle-SES homes and Nso farming villages in Cameroon, the Nso toddlers copied far fewer adult-demonstrated actions on toys than did the German toddlers (Borchert et al., 2013). Nso caregivers rarely create such child-focused teaching situations. Rather they expect children to imitate adult behaviors without prompting. Nso children are motivated to do so because they want to be included in the major activities of their community.

Earlier we saw how infants and toddlers create new schemes by acting on the physical world (Piaget) and how certain skills become better developed as children represent their experiences more efficiently and meaningfully (information processing). Vygotsky adds a third dimension to our understanding by emphasizing that many aspects of cognitive development are socially mediated. The Cultural Influences box on page 168 presents additional evidence for this idea, and we will see even more in the next section.

## Ask yourself

**CONNECT** List techniques that parents can use to promote development of categorization in infancy and toddlerhood, and explain why each is effective.

**APPLY** When Timmy was 18 months old, his mother stood behind him, helping him throw a large ball into a box. As his skill improved, she stepped back, letting him try on his own. Using Vygotsky’s ideas, explain how Timmy’s mother is supporting his cognitive development.

**REFLECT** Describe your earliest autobiographical memory. How old were you when the event occurred? Do your recollections fit with research on infantile amnesia?

## Individual Differences in Early Mental Development

**5.8** Describe the mental testing approach and the extent to which infant tests predict later performance.

**5.9** Discuss environmental influences on early mental development, including home, child care, and early intervention for at-risk infants and toddlers.

Because of Grace’s deprived early environment, Kevin and Monica had a child psychologist give her one of many tests available for assessing mental development in infants and toddlers. Worried about Timmy’s progress, Vanessa also arranged for him to be tested. At age 22 months, he had only a handful of words in his vocabulary, played in a less mature way than Caitlin and Grace, and seemed restless and overactive.

The cognitive theories we have just discussed try to explain the *process* of development—how children’s thinking changes. Mental tests, in contrast, focus on *individual differences*: They measure variations in developmental progress, arriving at scores that *predict* future performance, such as later intelligence, school achievement, and adult vocational success. This concern with prediction arose about a century ago, when French psychologist Alfred Binet designed the first successful intelligence test, which predicted school achievement (see Chapter 1). It inspired the design of many new tests, including ones that measure intelligence at very early ages.

## Infant and Toddler Intelligence Tests

Accurately measuring infants’ intelligence is a challenge because babies cannot answer questions or follow directions. All we can do is present them with stimuli, coax them to respond, and observe their behavior. As a result, most infant tests emphasize perceptual and motor responses. But increasingly, tests are being developed that also tap early language, cognition, and social behavior, especially with older infants and toddlers.

One commonly used test, the *Bayley Scales of Infant and Toddler Development*, is suitable for children between 1 month and 3½ years. The most recent edition, the Bayley-III, has three main subtests: (1) the Cognitive Scale, which includes such items as attention to familiar and unfamiliar objects, looking for a fallen object, and pretend play; (2) the Language Scale, which assesses understanding and expression of language—for example, recognition of objects and people, following simple directions, and naming objects and pictures; and (3) the Motor Scale, which includes gross and fine motor skills, such as grasping, sitting, stacking blocks, and climbing stairs (Bayley, 2005).

Two additional Bayley-III scales depend on parental report: (4) the Social-Emotional Scale, which asks caregivers about such behaviors as ease of calming, social responsiveness, and imitation

## Cultural Influences

### Social Origins of Make-Believe Play

One of the activities my husband, Ken, used to do with our two young sons was to bake pineapple upside-down cake, a favorite treat. One day when a cake was in the making, 21-month-old Peter stood on a chair at the kitchen sink, busily pouring water from one cup to another.

“He’s in the way, Dad!” complained 4-year-old David.

“Maybe if we let him help, he’ll give us room,” Ken suggested. As David stirred the batter, Ken poured some into a small bowl for Peter, moved his chair to the side of the sink, and handed him a spoon.

“Here’s how you do it, Petey,” instructed David, with a superior air. Peter watched as David stirred, then tried to copy. When it was time to pour the batter, Ken helped Peter hold and tip the small bowl.

“Time to bake it,” said Ken.

“Bake it, bake it,” repeated Peter, watching Ken slip the pan into the oven.

Several hours later, we observed one of Peter’s earliest instances of make-believe play. He got his pail from the sandbox and, after filling it with a handful of sand, carried it into the kitchen. “Bake it, bake it,” Peter called to Ken. Together, father and son placed the pretend cake in the oven.

Piaget and his followers concluded that toddlers discover make-believe independently, once they are capable of representational schemes. Vygotsky challenged this view, pointing out that society provides children with opportunities to represent culturally meaningful activities in play. Make-believe, like other complex mental activities, is first learned under the guidance of experts (Meyers & Berk, 2014). In the example just described, Peter extended his capacity to represent daily events when Ken drew him into the baking task and helped him act it out in play.

In Western middle-SES families, make-believe is culturally cultivated and scaffolded by adults, who value it as a developmentally beneficial activity (Gaskins, 2014). During make-believe, mothers, especially, offer toddlers a rich array of cues that they are pretending—looking and smiling at the child more, making more exaggerated movements, and using

FARZANA WAHIDY/AP IMAGES

In cultures where sibling caregiving is common, make-believe play is more frequent and complex with older siblings than with mothers. These Afghan children play “wedding,” dressing the youngest as a bride.

more “we” talk (acknowledging that pretending is a joint endeavor) than they do during the same real-life event (Lillard, 2007). These cues encourage toddlers to join in and probably facilitate their ability to distinguish pretend from real acts, which strengthens over the second and third years (Ma & Lillard, 2006).

Also, when adults participate, toddlers’ make-believe is more elaborate (Keren et al., 2005). They are more likely to combine pretend acts into complex sequences, as Peter did when he put sand in the bucket (making the batter), carried it into the kitchen, and, with Ken’s help, put it in the oven (baking the cake). The more parents pretend with their toddlers, the more time their children devote to make-believe (Cote & Bornstein, 2009).

In some cultures, such as those of Indonesia and Mexico, where play is viewed as solely a child’s activity and sibling caregiving is common, make-believe is more frequent and complex with older siblings than with mothers. As early as age 3 to 4, children provide rich, challenging stimulation to their younger brothers and sisters, take these teaching responsibilities seriously, and, with age, become better at adjusting their playful interactions to the younger child’s needs (Zukow-Goldring, 2002). In a study of Zinacanteco Indian children of southern Mexico, by age 8,

sibling teachers were highly skilled at showing 2-year-olds how to play at everyday tasks, such as washing and cooking (Maynard, 2002). They often guided toddlers verbally and physically through the task and provided feedback.

In Western middle-SES families, older siblings less often teach deliberately but still serve as influential models of playful behavior. In New Zealand families of European descent, when both a parent and an older sibling were available, toddlers more often imitated the actions of the sibling, especially when siblings engaged in make-believe (Barr & Hayne, 2003).

As we will see in Chapter 7, make-believe play is a major means through which children extend their cognitive and social skills and learn about important activities in their culture (Nielsen, 2012). Vygotsky’s theory, and the findings that support it, tells us that providing a stimulating physical environment is not enough to promote early cognitive development. In addition, toddlers must be invited and encouraged by more skilled members of their culture to participate in the social world around them. Parents and teachers can enhance early make-believe by playing often with toddlers, guiding and elaborating their make-believe themes.

A trained examiner administers a test based on the Bayley Scales of Infant Development to a 1-year-old sitting in her mother's lap. Compared with earlier editions, the Bayley-III Cognitive and Language Scales better predict preschool mental test performance.

in play; and (5) the Adaptive Behavior Scale, which asks about adaptation to the demands of daily life, including communication, self-control, following rules, and getting along with others.

**Computing Intelligence Test Scores.** Intelligence tests for infants, children, and adults are scored in much the same way—by computing an **intelligence quotient (IQ)**, which indicates the extent to which the raw score (number of items passed) deviates from the typical performance of same-age individuals. To make this comparison possible, test designers engage in **standardization**—giving the test to a large, representative sample and using the results as the *standard* for interpreting scores. The standardization sample for the Bayley-III included 1,700 infants, toddlers, and young preschoolers, reflecting the U.S. population in SES and ethnic diversity.

Within the standardization sample, performances at each age level form a **normal distribution**, in which most scores cluster around the mean, or average, with progressively fewer falling toward the extremes (see Figure 5.8). This *bell-shaped*

**FIGURE 5.8** Normal distribution of intelligence test scores. To determine what percentage of same-age individuals in the population a person with a certain IQ outperformed, add the figures to the left of that IQ score. For example, an 8-year-old child with an IQ of 115 scored better than 84 percent of the population of 8-year-olds.

*distribution* results whenever researchers measure individual differences in large samples. When intelligence tests are standardized, the mean IQ is set at 100. An individual's IQ is higher or lower than 100 by an amount that reflects how much his or her test performance deviates from the standardization-sample mean.

The IQ offers a way of finding out whether an individual is ahead, behind, or on time (average) in mental development compared with others of the same age. For example, if Timmy's score is 100, then he did better than 50 percent of his agemates. A child with an IQ of 85 did better than only 16 percent, whereas a child with an IQ of 130 outperformed 98 percent. The IQs of 96 percent of individuals fall between 70 and 130; only a few achieve higher or lower scores.

### Predicting Later Performance from Infant Tests.

Despite careful construction, most infant tests—including previous editions of the Bayley—predict later intelligence poorly. Infants and toddlers easily become distracted, fatigued, or bored during testing, so their scores often do not reflect their true abilities. And infant perceptual and motor items differ from the tasks given to older children, which increasingly emphasize verbal, conceptual, and problem-solving skills. In contrast, the Bayley-III Cognitive and Language Scales, which better dovetail with childhood tests, are good predictors of preschool mental test performance (Albers & Grieve, 2007). But because most infant test scores do not tap the same dimensions of intelligence assessed in older children, they usually are conservatively labeled **developmental quotients (DQs)** rather than IQs.

Infant tests are somewhat better at making long-term predictions for extremely low-scoring babies. Today, they are largely used for *screening*—helping to identify for further observation and intervention babies who are likely to have developmental problems.

As an alternative to infant tests, some researchers have turned to information-processing measures, such as habituation, to assess early mental progress. Their findings show that speed of habituation and recovery to novel visual stimuli is among the best available infant predictors of IQ from early childhood through early adulthood (Fagan, Holland, & Wheeler, 2007; Kavšek, 2004). Habituation and recovery seem to be an especially effective early index of intelligence because they assess memory as well as quickness and flexibility of thinking, which underlie intelligent behavior at all ages (Colombo et al., 2004). The consistency of these findings has prompted designers of the Bayley-III to include items that tap such cognitive skills as habituation, object permanence, and categorization.

## Early Environment and Mental Development

In Chapter 2, we indicated that intelligence is a complex blend of hereditary and environmental influences. Many studies have examined the relationship of environmental factors to infant and toddler mental test scores. As we consider this evidence, you will encounter findings that highlight the role of heredity as well.

## Applying what we Know

### Features of a High-Quality Home Life for Infants and Toddlers: The HOME Infant–Toddler Subscales

HOME SUBSCALE	SAMPLE ITEM
Organization of the physical environment	Child's play environment appears safe and free of hazards.
Provision of appropriate play materials	Parent provides toys or interesting activities for child during observer's visit.
Emotional and verbal responsiveness of the parent	Parent caresses or kisses child at least once during observer's visit. Parent spontaneously speaks to child twice or more (excluding scolding) during observer's visit.
Parental acceptance of the child	Parent does not interfere with child's actions or restrict child's movements more than three times during observer's visit.
Parental involvement with the child	Parent tends to keep child within visual range and to look at child often during observer's visit.
Opportunities for variety in daily stimulation	Child eats at least one meal per day with mother and/or father, according to parental report. Child frequently has a chance to get out of house (for example, accompanies parent on trips to grocery store).

Sources: Bradley, 1994; Bradley et al., 2001. A brief, exclusively observational HOME instrument taps the first three subscales only (Rijlaarsdam et al., 2012).

**Home Environment.** The **Home Observation for Measurement of the Environment (HOME)** is a checklist for gathering information about the quality of children's home lives through observation and parental interview (Caldwell & Bradley, 1994). Applying What We Know above lists factors measured by the HOME Infant–Toddler Subscales—the most widely used home environment measure during the first three years (Rijlaarsdam et al., 2012).

Each HOME subscale is positively related to toddlers' mental test performance. And although low SES is consistently linked to lower HOME scores, an organized, stimulating physical setting and parental affection, involvement, and encouragement of new skills consistently predict better language and IQ scores in toddlerhood and early childhood across SES and ethnic groups (Bornstein, 2015; Fuligni, Han, & Brooks-Gunn, 2004; Linver, Martin, & Brooks-Gunn, 2004; Tong et al., 2007). The extent to which parents talk to infants and toddlers is particularly important. It contributes strongly to early language progress, which, in turn, predicts intelligence and academic achievement in elementary school (Hart & Risley, 1995; Hoff, 2013).

Yet we must interpret these correlational findings cautiously. Parents who are more intelligent may provide better experiences while also giving birth to brighter children, who evoke more stimulation from their parents. Research supports this hypothesis, which refers to *gene–environment correlation* (see Chapter 2, pages 68–69) (Saudino & Plomin, 1997). But parent–child shared heredity does not account for the entire association between home environment and mental test scores. Family living conditions—both HOME scores and affluence of the surrounding neighborhood—continue to predict children's IQ beyond the contribution of parental IQ and education (Chase-Lansdale et al., 1997; Klebanov et al., 1998).

How can the research summarized so far help us understand Vanessa's concern about Timmy's development? Ben, the psychologist who tested Timmy, found that he scored only slightly below average. Ben talked with Vanessa about her child-rearing practices and watched her play with Timmy. A single parent who

A father plays actively and affectionately with his baby. Parental warmth, attention, and verbal communication predict better language and IQ scores in toddlerhood and early childhood.

worked long hours, Vanessa had little energy for Timmy at the end of the day. Ben also noticed that Vanessa, anxious about Timmy's progress, was intrusive: She interfered with his active behavior and bombarded him with directions: "That's enough ball play. Stack these blocks."

Ben explained that young children who experience intrusive parenting are likely to be distractible and withdrawn and do poorly on mental tests—negative outcomes that persist unless parenting improves (Clincy & Mills-Koonce, 2013; Rubin, Coplan, & Bowker, 2009). Ben coached Vanessa in how to interact sensitively with Timmy while assuring her that Timmy's current performance need not forecast his future development. Warm, responsive parenting that builds on toddlers' current capacities is a much better indicator than an early mental test score of how children will do later.

**Infant and Toddler Child Care.** Today, more than 60 percent of U.S. mothers with a child under age 2 are employed (U.S. Census Bureau, 2015d). Child care for infants and toddlers has become common, and its quality—though not as influential as parenting—affects mental development.

Research consistently shows that infants and young children exposed to poor-quality child care—whether they come from middle- or low-SES homes—score lower on measures of cognitive, language, academic, and social skills during the preschool, elementary, and secondary school years (Belsky et al., 2007b; Burchinal et al., 2015; Dearing, McCartney, & Taylor, 2009; NICHD Early Child Care Research Network, 2000b, 2001, 2003b, 2006; Vandell et al., 2010). In contrast, good child care can reduce the negative impact of a stressed, poverty-stricken home life, and it sustains the benefits of growing up in an economically advantaged family (Burchinal, Kainz, & Cai, 2011; McCartney et al., 2007). As Figure 5.9 illustrates, the Early Childhood Longitudinal Study, which included a large sample of U.S. children diverse in SES and ethnicity followed from birth through the preschool years, confirmed the importance of continuous high-quality child care from infancy through the preschool years (Li et al., 2013).

In contrast to most European countries and to Australia and New Zealand, where child care is nationally regulated and funded to ensure its quality, reports on U.S. child care raise serious concerns. Standards are set by the individual states and vary widely. In studies of quality, only 20 to 25 percent of U.S. child-care centers and family child-care homes provided infants and toddlers with sufficiently positive, stimulating experiences to promote healthy psychological development. Most settings offered substandard care, with infants and toddlers faring better when cared for by a relative (NICHD Early Childhood Research Network, 2000a, 2004). Furthermore, the cost of child care in the United States is high: On average, full-time center-based care for one infant consumes from 7 to 19 percent of the median income for couples and over 40 percent for single mothers (Child Care

**FIGURE 5.9** Relationship of child-care quality in infancy–toddlerhood and the preschool years to language development at age 5. When a nationally representative sample of more than 1,300 children was followed over the first five years, language scores were highest for those experiencing high-quality child care in both infancy–toddlerhood and the preschool years, intermediate for those experiencing high-quality care in just one of these periods, and lowest for those experiencing poor-quality care in both periods. Cognitive, literacy, and math scores also showed this pattern. (Based on Li et al, 2013)

Aware, 2015). The cost of a family child-care home is only slightly lower.

Unfortunately, many U.S. children from low-income families experience inadequate child care (NICHD Early Child Care Research Network, 2005; Torquati et al., 2011). But U.S. settings providing the very worst care tend to serve middle-income families. These parents are especially likely to place their children in for-profit centers, where quality tends to be lowest. Economically disadvantaged children more often attend publicly subsidized, nonprofit centers, which are better equipped with learning materials and have smaller group sizes and more favorable teacher–child ratios (Johnson, Ryan, & Brooks-Gunn, 2012). Still, child-care quality for low-income children is often substandard.

See Applying What We Know on page 172 for signs of high-quality care for infants and toddlers, based on standards for **developmentally appropriate practice**. These standards, devised by the U.S. National Association for the Education of Young Children, specify program characteristics that serve young children's developmental and individual needs, based on both current research and consensus among experts. Caitlin, Grace, and Timmy are fortunate to be in family child care that meets these standards.

Child care in the United States is affected by a macrosystem of individualistic values and weak government regulation and funding. Furthermore, many parents think that their children's

## Applying what we Know

### Signs of Developmentally Appropriate Infant and Toddler Child Care

PROGRAM CHARACTERISTICS	SIGNS OF QUALITY
Physical setting	Indoor environment is clean, in good repair, well-lit, and well-ventilated. Fenced outdoor play space is available. Setting does not appear overcrowded when children are present.
Toys and equipment	Play materials are appropriate for infants and toddlers and are stored on low shelves within easy reach. Cribs, highchairs, infant seats, and child-sized tables and chairs are available. Outdoor equipment includes small riding toys, swings, slide, and sandbox.
Caregiver–child ratio	In child-care centers, caregiver–child ratio is no greater than 1 to 3 for infants and 1 to 6 for toddlers. Group size (number of children in one room) is no greater than 6 infants with 2 caregivers and 12 toddlers with 2 caregivers. In family child care, caregiver is responsible for no more than 6 children; within this group, no more than 2 are infants and toddlers. Staffing is consistent, so infants and toddlers can form relationships with particular caregivers.
Daily activities	Daily schedule includes times for active play, quiet play, naps, snacks, and meals. It is flexible rather than rigid, to meet the needs of individual children. Atmosphere is warm and supportive, and children are never left unsupervised.
Interactions among adults and children	Caregivers respond promptly to infants' and toddlers' distress; hold them and talk, sing, and read to them; and interact with them in a manner that respects the individual child's interests and tolerance for stimulation.
Caregiver qualifications	Caregiver has some training in child development, first aid, and safety.
Relationships with parents	Parents are welcome anytime. Caregivers talk frequently with parents about children's behavior and development.
Licensing and accreditation	Child-care setting, whether a center or a home, is licensed by the state. In the United States, voluntary accreditation by the National Association for the Education of Young Children ( <a href="http://www.naeyc.org/accreditation">www.naeyc.org/accreditation</a> ), or the National Association for Family Child Care ( <a href="http://www.nafcc.org">www.nafcc.org</a> ) is evidence of an especially high-quality program.

Sources: Copple & Bredekamp, 2009.

child-care experiences are better than they really are (Torquati et al., 2011). Unable to identify good care, or without the financial means to purchase it, they do not demand it. In recent years, the U.S. federal government and some states have allocated additional funds to subsidize child-care costs, especially for low-income families (Matthews, 2014). Though far from meeting the need, this increase in resources has had a positive impact on child-care quality and accessibility.

### LOOK and LISTEN

Ask several employed parents of infants or toddlers to describe what they sought in a child-care setting, along with challenges they faced in finding child care. How knowledgeable are the parents about the ingredients of high-quality care?

## Early Intervention for At-Risk Infants and Toddlers

Children living in persistent poverty are likely to show gradual declines in intelligence test scores and to achieve poorly when they reach school age (Schoon et al., 2012). These problems are largely due to stressful home environments that undermine

children's ability to learn and increase the likelihood that they will remain poor as adults. A variety of intervention programs have been developed to break this tragic cycle of poverty. Although most begin during the preschool years (we will discuss these in Chapter 7), some start during infancy and continue through early childhood.

In center-based interventions, children attend an organized child-care or preschool program where they receive educational, nutritional, and health services, and their parents receive child-rearing and other social service supports. In home-based interventions, a skilled adult visits the home and works with parents, teaching them how to stimulate a young child's development. In most programs of either type, participating children score higher than untreated controls on mental tests by age 2. The earlier intervention begins, the longer it lasts, and the greater its scope and intensity, the better participants' cognitive and academic performance throughout childhood and adolescence (Ramey, Ramey, & Lanzi, 2006; Sweet & Appelbaum, 2004).

The Carolina Abecedarian Project illustrates these favorable outcomes. In the 1970s, more than 100 infants from poverty-stricken families, ranging in age from 3 weeks to 3 months, were randomly assigned to either a treatment group or a control group. Treatment infants were enrolled in full-time, year-round child care through the preschool years. There they received stimulation

aimed at promoting motor, cognitive, language, and social skills and, after age 3, literacy and math concepts. Special emphasis was placed on rich, responsive adult–child verbal communication. All children received nutrition and health services; the primary difference between treatment and controls was the intensive child-care experience.

By 12 months of age, treatment children scored higher in IQ, an advantage they sustained until last tested—at age 21. In addition, throughout their school years, treatment youths achieved higher scores in reading and math. These gains translated into reduced enrollment in special education, more years of schooling completed, higher rates of college enrollment and graduation, more consistent employment, and lower rates of adolescent parenthood (Campbell et al., 2001, 2002, 2012).

Recognition of the power of intervening as early as possible led the U.S. Congress to provide limited funding for services directed at infants and toddlers who already have serious developmental problems or who are at risk for problems because of poverty. Early Head Start, begun in 1995, currently has 1,000 sites serving about 110,000 low-income children and their families (Walker, 2014). A recent evaluation, conducted when children reached age 3, showed that Early Head Start led to warmer, more stimulating parenting, a reduction in harsh discipline, gains in cognitive and language development, and lessening of child aggression (Love, Chazan-Cohen, & Raikes, 2007; Love et al., 2005; Raikes et al., 2010). The strongest effects occurred at sites mixing center- and home-visiting services.

By age 5, however, the benefits of Early Head Start had declined or disappeared, and a follow-up in fifth grade showed

no persisting gains (U.S. Department of Health and Human Services, 2006; Vogel et al., 2010). One speculation is that more intentional educational experiences extending through the preschool years—as in the Abecedarian project—would increase the lasting impact of Early Head Start (Barnett, 2011). Although Early Head Start is in need of refinement, it is a promising beginning at providing U.S. infants and toddlers living in poverty with publicly supported intervention.

## Ask yourself

**CONNECT** Using what you learned about brain development in Chapter 4, explain why it is best to initiate intervention for poverty-stricken children in the first two years rather than later.

**APPLY** Fifteen-month-old Manuel's developmental quotient (DQ) is 115. His mother wants to know exactly what this means and what she should do to support his mental development. How would you respond?

**REFLECT** Suppose you were seeking a child-care setting for your baby. What would you want it to be like, and why?

## Language Development

**5.10** Describe theories of language development, and indicate the emphasis each places on innate abilities and environmental influences.

**5.11** Describe major language milestones in the first two years, individual differences, and ways adults can support early language development.

Improvements in perception and cognition during infancy pave the way for an extraordinary human achievement—language. In Chapter 4, we saw that by the second half of the first year, infants make dramatic progress in distinguishing the basic sounds of their language and in segmenting the flow of speech into word and phrase units. They also start to comprehend some word meanings and, around 12 months of age, say their first understandable word. Sometime between 1½ and 2 years, toddlers combine two words (MacWhinney, 2015). By age 6, children understand the meaning of about 14,000 words, speak in elaborate sentences, and are skilled conversationalists.

To appreciate this awesome task, think about the many abilities involved in your own flexible use of language. When you speak, you must select words that match the underlying concepts you want to convey. To be understood, you must pronounce words correctly. Then you must combine them into phrases and sentences using a complex set of grammatical rules. Finally, you must follow the rules of everyday conversation—taking turns, making comments relevant to what your partner just said, and using an appropriate tone of voice. How do infants and toddlers make such remarkable progress in launching these skills?

This Early Head Start program provides rich, educational experiences for toddlers plus parent education and family supports. The most favorable outcomes of Early Head Start result from mixing center- and home-visiting services.

## Theories of Language Development

In the 1950s, researchers did not take seriously the idea that very young children might be able to figure out important properties of language. Children's regular and rapid attainment of language milestones suggested a process largely governed by maturation, inspiring the nativist perspective on language development. In recent years, new evidence has spawned the interactionist perspective, which emphasizes the joint roles of children's inner capacities and communicative experiences.

**The Nativist Perspective.** According to linguist Noam Chomsky's (1957) *nativist* theory, language is a unique human accomplishment, etched into the structure of the brain. Focusing on grammar, Chomsky reasoned that the rules of sentence organization are too complex to be directly taught to or discovered by even a cognitively sophisticated young child. Rather, he proposed that all children have a **language acquisition device (LAD)**, an innate system that contains a *universal grammar*, or set of rules common to all languages. It enables children, no matter which language they hear, to understand and speak in a rule-oriented fashion as soon as they pick up enough words.

Are children innately primed to acquire language? Recall from Chapter 4 that newborn babies are remarkably sensitive to speech sounds. And children everywhere reach major language milestones in a similar sequence (Parish-Morris, Golinkoff, & Hirsh-Pasek, 2013). Also, the ability to master a grammatically complex language system seems unique to humans, as efforts to teach language to nonhuman primates—using either specially devised artificial symbol systems or sign language—have met with limited success. Even after extensive training, chimpanzees (who are closest to humans in terms of evolution) master only a basic vocabulary and short word combinations, and they produce these far less consistently than human preschoolers (Tomasello, Call, & Hare, 2003).

Furthermore, evidence that childhood is a *sensitive period* for language acquisition is consistent with Chomsky's idea of a biologically based language program. Researchers have examined the language competence of deaf adults who acquired their first language—American Sign Language (ASL), a gestural system just as complex as any spoken language—at different ages. The later learners, whose parents chose to educate them through the oral method, which relies on speech and lip-reading, did not acquire spoken language because of their profound deafness. Consistent with the sensitive-period notion, those who learned ASL in adolescence or adulthood never became as proficient as those who learned in childhood (Mayberry, 2010; Newport, 1991; Singleton & Newport, 2004).

Although it is now widely accepted that humans have a unique capacity to acquire language, Chomsky's theory has been contested on several grounds. First, researchers have had great difficulty specifying Chomsky's universal grammar. Chomsky's critics doubt that one set of rules can account for the extraordinary variation in grammatical forms among the world's 5,000 to

8,000 languages. Second, children do not acquire language as quickly as nativist theory suggests. They refine and generalize many grammatical forms gradually, engaging in much piecemeal learning and making errors along the way (Evans & Levinson, 2009; MacWhinney, 2015). As we will see in Chapter 9, complete mastery of some grammatical forms, such as the passive voice, is not achieved until well into middle childhood. This suggests that more experimentation and learning are involved than Chomsky assumed.

Finally, recall from Chapter 4 that for most people, language is housed largely in the left hemisphere of the cerebral cortex, consistent with Chomsky's notion of a brain prepared to process language. But our discussion also revealed that language areas in the cortex *develop* as children acquire language. Although the left hemisphere is biased for language processing, if it is injured in the early years, other regions take over (see page 122 in Chapter 4). Thus, left-hemispheric localization, though typical, is not necessary for effective language processing.

**The Interactionist Perspective.** Recent ideas about language development emphasize *interactions* between inner capacities and environmental influences. One type of interactionist theory applies the information-processing perspective to language development. A second type emphasizes social interaction.

Some information-processing theorists assume that children make sense of their complex language environments by applying powerful cognitive capacities of a general kind (MacWhinney, 2015; Munakata, 2006; Saffran, 2009). These theorists note that brain regions housing language also govern similar perceptual

© LAURA DWIGHT PHOTOGRAPHY

Infants communicate from the very beginning of life. How will this child become a fluent speaker of her native language within just a few years? Theorists disagree sharply.

**TABLE 5.3**  
**Milestones of Language Development During the First Two Years**

APPROXIMATE AGE	MILESTONE
2 months	Infants coo, making pleasant vowel sounds.
4 months on	Infants observe with interest as the caregiver plays turn-taking games, such as pat-a-cake and peekaboo.
6 months on	Infants babble, adding consonants to their cooing sounds and repeating syllables. By 7 months, babbling starts to include many sounds of spoken languages. Infants begin to comprehend a few commonly heard words.
8–12 months	Infants become more accurate at establishing joint attention with the caregiver, who often verbally labels what the baby is looking at. Infants actively participate in turn-taking games, trading roles with the caregiver. Infants use preverbal gestures, such as showing and pointing, to influence others' goals and behavior and to convey information.
12 months	Babbling includes sound and intonation patterns of the child's language community. Speed and accuracy of word comprehension increase rapidly. Toddlers say their first recognizable word.
18–24 months	Spoken vocabulary expands from about 50 to 200 to 250 words. Toddlers combine two words.

and cognitive abilities, such as the capacity to analyze musical and visual patterns (Saygin, Leech, & Dick, 2010).

Other theorists blend this information-processing view with Chomsky's nativist perspective. They agree that infants are amazing statistical analyzers of speech and other information. But, they argue, these capacities probably are not sufficient to account for mastery of higher-level aspects of language, such as intricate grammatical structures (Aslin & Newport, 2012). They also point out that grammatical competence may depend more on specific brain structures than the other components of language. When 2- to 2½-year-olds and adults listened to short sentences—some grammatically correct, others with phrase-structure violations—both groups showed similarly distinct ERP brain-wave patterns for each sentence type in the left frontal and temporal lobes of the cerebral cortex (Oberecker & Friederici, 2006). This suggests that 2-year-olds process sentence structures using the same neural system as adults do. Furthermore, in studies of older children and adults with left-hemispheric brain damage, grammar is more impaired than other language functions (Curtiss & Schaeffer, 2005).

Still other interactionists emphasize that children's social skills and language experiences are centrally involved in language development. In this *social-interactionist* view, an active child strives to communicate, which cues her caregivers to provide appropriate language experiences. These experiences, in turn, help the child relate the content and structure of language to its social meanings (Bohannon & Bonvillian, 2013; Chapman, 2006).

Among social interactionists, disagreement continues over whether or not children are equipped with specialized language structures in the brain (Hsu, Chater, & Vitányi, 2013; Lidz, 2007; Tomasello, 2006). Nevertheless, as we chart the course of language development, we will encounter much support for their central premise—that children's social competencies and language experiences greatly affect their language progress. In reality, native endowment, cognitive-processing strategies, and social experience probably operate in different balances with respect to each aspect of language. Table 5.3 provides an overview of early language milestones that we will examine in the next few sections.

## Getting Ready to Talk

Before babies say their first word, they make impressive progress toward understanding and speaking their native tongue. They listen attentively to human speech, and they make speechlike sounds. As adults, we can hardly help but respond.

**Cooing and Babbling.** Around 2 months, babies begin to make vowel-like noises, called **cooing** because of their pleasant “oo” quality. Gradually, consonants are added, and around 6 months, **babbling** appears, in which infants repeat consonant–vowel combinations. With age, they increasingly babble in long strings, such as “bababababa” or “nanananana,” in an effort to gain control over producing particular sounds.

Babies everywhere (even those who are deaf) start babbling at about the same age and produce a similar range of early sounds. But for babbling to develop further, infants must be able to hear human speech. In babies with hearing impairments, these speechlike sounds are greatly delayed and limited in diversity of sounds (Bass-Ringdahl, 2010). And a deaf infant not exposed to sign language will stop babbling entirely (Oller, 2000).

Babies initially produce a limited number of sounds and then expand to a much broader range. Around 7 months, babbling starts to include many sounds of spoken languages. As caregivers respond to infant babbles, older infants become better at matching the sounds they hear in adult speech (Goldstein & Schwade, 2008). By 8 to 10 months, babbling reflects the sound and intonation patterns of the child's language community, some of which are transferred to their first words (Boysson-Bardies & Vihman, 1991).

Deaf infants exposed to sign language from birth babble with their hands much as hearing infants do through speech (Petitto & Marentette, 1991). Furthermore, hearing babies of deaf, signing parents produce babblelike hand motions with the rhythmic patterns of natural sign languages (Petitto et al., 2001, 2004). This sensitivity to language rhythm—evident in both spoken and signed babbling—supports both discovery and production of meaningful language units.

**Becoming a Communicator.** At birth, infants are prepared for some aspects of conversational behavior. For example, newborns initiate interaction through eye contact and terminate it by looking away. By 3 to 4 months, infants start to gaze in the same general direction adults are looking—a skill that becomes more accurate at 10 to 11 months, as babies realize that others' focus offers information about their communicative intentions (to talk about an object) or other goals (to obtain an object) (Brooks & Meltzoff, 2005; Senju, Csibra, & Johnson, 2008). This **joint attention**, in which the child attends to the same object or event as the caregiver, who often labels it, contributes greatly to early language development. Infants and toddlers who frequently experience it sustain attention longer, comprehend more language, produce meaningful gestures and words earlier, and show faster vocabulary development (Brooks & Meltzoff, 2008; Carpenter, Nagell, & Tomasello, 1998; Flom & Pick, 2003; Silvé, 2001).

Around 3 months, interactions between caregivers and babies begin to include *give-and-take*. Infants and mothers mutually imitate the pitch, loudness, and duration of each other's sounds. Mothers take the lead, imitating about twice as often as 3-month-olds, who limit their imitations to a handful of sounds they find easier to produce (Gratier & Devouche, 2011). Between 4 and 6 months, imitation extends to social games, as in pat-a-cake and peekaboo. At first, the parent starts the game and the baby is an amused observer. Gradually, infants join in, and by the end of the first year, they participate actively, trading roles with the caregiver. Through these imitative exchanges, babies

© TINA & GEIR/CORBIS

This baby uses a preverbal gesture to direct his father's attention. The father's verbal response ("I see that squirrel!") promotes the baby's transition to spoken language.

practice the turn-taking pattern of human conversation, a vital context for acquiring language and communication skills.

At the end of the first year, babies use *preverbal gestures* to direct adults' attention, influence their behavior, and convey helpful information (Tomasello, Carpenter, & Liszkowski, 2007). For example, Caitlin held up a toy to show it, pointed to the cupboard when she wanted a cookie, and pointed at her mother's car keys lying on the floor. Carolyn responded to these gestures and also labeled them ("That's your bear!" "You want a cookie!" "Oh, there are my keys!"). In this way, toddlers learn that using language leads to desired results.

The more time caregivers and infants spend in joint play with objects, the earlier and more often babies use preverbal gestures (Salomo & Liszkowski, 2013). Soon toddlers integrate words with gestures, using the gesture to expand their verbal message, as in pointing to a toy while saying "give" (Capirci et al., 2005). Gradually, gestures recede, and words become dominant. But the earlier toddlers form word-gesture combinations, the faster their vocabulary growth, the sooner they produce two-word utterances at the end of the second year, and the more complex their sentences at age 3½ (Huttenlocher et al., 2010; Rowe & Goldin-Meadow, 2009).

## First Words

In the middle of the first year, infants begin to understand word meanings. By 5 months, they respond to their own name, preferring to listen to it than to another word matched in stress pattern (Mandel, Jusczyk, & Pisoni, 1995). And when 6-month-olds listened to the word "Mommy" or "Daddy" while viewing side-by-

side videos of their parents, they looked longer at the video of the named parent (Tincoff & Jusczyk, 1999).

First recognizable spoken words, around 1 year, build on the sensorimotor foundations Piaget described and on categories children have formed. In a study tracking the first 10 words used by several hundred U.S. and Chinese (both Mandarin- and Cantonese-speaking) babies, important people (“Mama,” “Dada”), common objects (“ball,” “bread”), and sound effects (“woof-woof,” “vroom”) were mentioned most often. Action words (“hit,” “grab,” “hug”) and social routines (“hi,” “bye”), though also appearing in all three groups, were more often produced by Chinese than U.S. babies, and the Chinese babies also named more important people—differences we will consider shortly (Tardif et al., 2008). In their first 50 words, toddlers rarely name things that just *sit there*, like “table” or “vase.”

When young children first learn words, they sometimes apply them too narrowly, an error called **underextension**. At 16 months, Caitlin used “bear” only to refer to the worn and tattered bear she carried nearly constantly. As vocabulary expands, a more common error is **overextension**—applying a word to a wider collection of objects and events than is appropriate. For example, Grace used “car” for buses, trains, trucks, and fire engines. Toddlers’ overextensions reflect their sensitivity to categories (MacWhinney, 2005). They apply a new word to a group of similar experiences: “car” to wheeled objects, “open” to opening a door, peeling fruit, and untying shoelaces. This suggests that children often overextend deliberately because they have difficulty recalling or have not acquired a suitable word. And when a word is hard to pronounce, toddlers are likely to substitute a related one they can say (Bloom, 2000). As vocabulary expands and pronunciation improves, overextensions gradually decline.

Overextensions illustrate another important feature of language development: the distinction between language *production* (the words and word combinations children use) and language *comprehension* (the language they understand). At all ages, comprehension develops ahead of production. A 2-year-old who refers to trucks, trains, and bikes as “car” may look at or point to these objects correctly when given their names (Naigles & Gelman, 1995). Still, the two capacities are related. The speed and accuracy of toddlers’ comprehension of spoken language increase dramatically over the second year. And toddlers who are faster and more accurate in comprehension tend to show more rapid growth in words understood and produced over the following year (Fernald & Marchman, 2012). Quick comprehension frees space in working memory for picking up new words and for the more demanding task of using them to communicate.

## The Two-Word Utterance Phase

Young toddlers add to their spoken vocabularies at a rate of one to three words per week. Because gains in word production between 18 and 24 months are so impressive (one or two words per day), many researchers concluded that toddlers undergo a

*sprint in vocabulary*—a transition from a slower to a faster learning phase. In actuality, most children show a steady increase in rate of word learning that continues through the preschool years (Ganger & Brent, 2004).

How do toddlers build their vocabularies so quickly? In the second year, they improve in ability to categorize experience, recall words, and understand others’ social cues to meaning, such as eye gaze, pointing, and handling objects (Golinkoff & Hirsh-Pasek, 2006; Liszkowski, Carpenter, & Tomasello, 2007). In Chapter 7, we will consider young children’s diverse strategies for word learning.

Once toddlers produce 200 to 250 words, they start to combine two words: “Mommy shoe,” “go car,” “more cookie.” These two-word utterances are called **telegraphic speech** because, like a telegram, they focus on high-content words, omitting smaller, less important ones (“can,” “the,” “to”).

Two-word speech consists largely of simple formulas (“more + *X*,” “eat + *X*”), with different words inserted in the “*X*” position. Toddlers rarely make gross grammatical errors, such as saying “chair my” instead of “my chair.” But their word-order regularities are usually copies of adult word pairings, as when the parent says, “How about *more sandwich?*” or “Let’s see if you can *eat the berries.*” This suggests that at first, young children rely on “concrete pieces of language” they often hear, gradually generalizing from those pieces to word-order and other grammatical rules (Bannard, Lieven, & Tomasello, 2009; MacWhinney, 2015). As we will see in Chapter 7, children master grammar steadily over the preschool years.

## Individual and Cultural Differences

Although children typically produce their first word around their first birthday, the range is large, from 8 to 18 months—variation due to a complex blend of genetic and environmental influences. Earlier we saw that Timmy’s spoken language was delayed, in part because of Vanessa’s tense, directive communication with him. But Timmy is also a boy, and girls are slightly ahead of boys in early vocabulary growth (Van Hulle, Goldsmith, & Lemery, 2004). The most common explanation is girls’ faster rate of physical maturation, which is believed to promote earlier development of the left cerebral hemisphere.

Temperament matters, too. For example, shy toddlers often wait until they understand a great deal before trying to speak. Once they do speak, their vocabularies increase rapidly, although they remain slightly behind their age-mates (Spere et al., 2004).

Caregiver–child conversation—especially, the richness of adults’ vocabularies—also plays a strong role (Huttenlocher et al., 2010). Commonly used words for objects appear early in toddlers’ speech, and the more often their caregivers use a particular noun, the sooner young children produce it (Goodman, Dale, & Li, 2008). Mothers talk more to toddler-age girls than to boys, and parents converse less often with shy than with sociable children (Leaper, Anderson, & Sanders, 1998; Patterson & Fisher, 2002).

## Applying what we Know

### Supporting Early Language Learning

STRATEGY	CONSEQUENCE
Respond to coos and babbles with speech sounds and words.	Encourages experimentation with sounds that can later be blended into first words. Provides experience with the turn-taking pattern of human conversation.
Establish joint attention and comment on what child sees.	Predicts earlier onset of language and faster vocabulary development.
Play social games, such as pat-a-cake and peekaboo.	Provides experience with the turn-taking pattern of human conversation.
Engage toddlers in joint make-believe play.	Promotes all aspects of conversational dialogue.
Engage toddlers in frequent conversations.	Predicts faster early language development and academic success during the school years.
Read to toddlers often, engaging them in dialogues about picture books.	Provides exposure to many aspects of language, including vocabulary, grammar, communication skills, and information about written symbols and story structures.

Compared to their higher-SES agemates, children from low-SES homes usually have smaller vocabularies. By 18 to 24 months, they are slower at word comprehension and have acquired 30 percent fewer words (Fernald, Marchman, & Weisleder, 2013). Limited parent–child conversation and book reading are major factors. On average, a middle-SES child is read to for 1,000 hours between 1 and 5 years, a low-SES child for only 25 hours (Neuman, 2003).

Not surprisingly, rate of early vocabulary growth is a strong predictor of low-SES children’s vocabulary size at kindergarten entry, which forecasts their later literacy skills and academic success (Rowe, Raudenbush, & Goldin-Meadow, 2012). Higher-SES toddlers who lag behind their agemates in word learning have more opportunities to catch up in early childhood. Young children have distinct styles of early language learning. Caitlin and Grace, like most toddlers, used a **referential style**; their vocabularies consisted mainly of words that refer to objects. A smaller number of toddlers use an **expressive style**; compared to referential children, they produce many more social formulas and pronouns (“thank you,” “done,” “I want it”). These styles reflect early ideas about the functions of language. Caitlin and Grace, for example, thought words were for naming things. In contrast, expressive-style children believe words are for talking about people’s feelings and needs (Bates et al., 1994). The vocabularies of referential-style toddlers grow faster because all languages contain many more object labels than social phrases.

What accounts for a toddler’s language style? Rapidly developing referential-style children often have an especially active interest in exploring objects. They also eagerly imitate their parents’ frequent naming of objects (Masur & Rodemaker, 1999). Expressive-style children tend to be highly sociable, and their parents more often use verbal routines (“How are you?” “It’s no trouble”) that support social relationships (Goldfield, 1987).

The two language styles are also linked to culture. Object words (nouns) are particularly common in the vocabularies of English-speaking toddlers, but Chinese, Japanese, and Korean toddlers have more words for actions (verbs) and social routines. Mothers’ speech in each culture reflects this difference (Chan, Brandone, & Tardif, 2009; Chan et al., 2011; Choi & Gopnik, 1995; Fernald & Morikawa, 1993). American mothers frequently label objects when interacting with their babies. Asian mothers, perhaps because of a cultural emphasis on the importance of group membership, emphasize actions and social routines. Also, in Mandarin, sentences often begin with verbs, making action words especially salient to Mandarin-speaking toddlers.

At what point should parents be concerned if their child talks very little or not at all? If a toddler’s language development is greatly delayed when compared with the norms in Table 5.3 (page 175), then parents should consult the child’s doctor or a speech and language therapist. Late babbling may be a sign of slow language development that can be prevented with early intervention (Rowe, Raudenbush, & Goldin-Meadow, 2012). Some toddlers who do not follow simple directions or who, after age 2, have difficulty putting their thoughts into words may suffer from a hearing impairment or a language disorder that requires immediate treatment.

### Supporting Early Language Development

Consistent with the interactionist view, a rich social environment builds on young children’s natural readiness to acquire language. For a summary of how caregivers can consciously support early language development, see Applying What We Know above. Caregivers also do so unconsciously—through a special style of speech.

Adults in many cultures speak to babies in **infant-directed speech (IDS)**, a form of communication made up of short sentences with high-pitched, exaggerated expression, clear pronunciation, distinct pauses between speech segments, clear gestures to support verbal meaning, and repetition of new words in a variety of contexts (“See the *ball*,” “The *ball* bounced!”) (Fernald et al., 1989; O’Neill et al., 2005). Deaf parents use a similar style of communication when signing to their deaf babies (Masataka, 1996). From birth on, infants prefer IDS over other adult talk, and by 5 months they are more emotionally responsive to it (Aslin, Jusczyk, & Pisoni, 1998).

IDS builds on several communicative strategies we have already considered: joint attention, turn-taking, and caregivers’ sensitivity to toddlers’ preverbal gestures. In this example, Carolyn uses IDS with 18-month-old Caitlin:

- Caitlin:* “Go car.”  
*Carolyn:* “Yes, time to go in the car. Where’s your jacket?”  
*Caitlin:* [Looks around, walks to the closet.] “Dacket!”  
 [Points to her jacket.]  
*Carolyn:* “There’s that jacket! [Helps Caitlin into the jacket.] On it goes! Let’s zip up. [Zips up the jacket.] Now, say bye-bye to Grace and Timmy.”  
*Caitlin:* “Bye-bye, G-ace. Bye-bye, Te-te.”  
*Carolyn:* “Where’s your bear?”  
*Caitlin:* [Looks around.]  
*Carolyn:* [Pointing.] “See? By the sofa.” [Caitlin gets the bear.]

Parents constantly fine-tune the length and content of their utterances in IDS to fit children’s needs—adjustments that enable infants and toddlers to join in and that foster both language comprehension and production (Ma et al., 2011; Rowe, 2008). As we saw earlier, parent–toddler conversation strongly predicts language development and reading success during the school years.

Research also reveals that live interaction with a responsive adult is far better suited to spurring early language development than media sources. After a month’s regular exposure to a commercial video for babies that labeled common household objects, 12- to 18-month-olds did not add any more words to their vocabulary than non-viewing controls. Rather, toddlers in a comparison group whose parents spent time teaching them the words in everyday activities learned best (DeLoache et al., 2010). Consistent with these findings, a video format that allows an adult to interact responsively with a 2-year-old—as in a Skype session—is an effective context for acquiring new verbs (Roseberry, Hirsh-Pasek, & Golinkoff, 2014).

But toddler viewers are unable to learn language from TV or video unless programs are specially adapted for them. For example, 2½-year-olds fail to acquire new object labels from an on-screen conversation between two adults, unless the actors show clear evidence of reciprocal interaction, such as the speaker

© LAURA DWIGHT PHOTOGRAPHY

A mother speaks to her baby in short, clearly pronounced sentences with high-pitched, exaggerated intonation. This form of communication, called infant-directed speech, eases early language learning.

handing the object to her partner, who accepts it and imitates the speaker’s action (O’Doherty et al., 2011). Return to page 157 to review the *video deficit effect*, noting how these findings illustrate it.

Do social experiences that promote language development remind you of those that strengthen cognitive development in general? IDS and parent–child conversation create a *zone of proximal development* in which children’s language expands. In contrast, adult behaviors that are unresponsive to children’s needs or impatient with their efforts to talk result in immature language skills (Baumwell, Tamis-LeMonda, & Bornstein, 1997; Cabrera, Shannon, & Tamis-LeMonda, 2007). In the next chapter, we will see that adult sensitivity supports infants’ and toddlers’ emotional and social development as well.

## Ask yourself

**CONNECT** Cognition and language are interrelated. List examples of how cognition fosters language development. Next, list examples of how language fosters cognitive development.

**APPLY** Fran frequently corrects her 17-month-old son Jeremy’s attempts to talk and—fearing that he won’t use words—refuses to respond to his gestures. How might Fran be contributing to Jeremy’s slow language progress?

**REFLECT** Find an opportunity to speak to an infant or toddler. Did you use IDS? What features of your speech are likely to promote early language development, and why?

## Summary / chapter 5

### Piaget's Cognitive-Developmental Theory (p. 150)

#### 5.1 According to Piaget, how do schemes change over the course of development?

- By acting on the environment, children move through four stages in which psychological structures, or **schemes**, achieve a better fit with external reality.
- Schemes change in two ways: through **adaptation**, which is made up of two complementary activities—**assimilation** and **accommodation**; and through **organization**, the internal rearrangement of schemes into a strongly interconnected cognitive system.

#### 5.2 Describe major cognitive attainments of the sensorimotor stage.

- In the **sensorimotor stage**, the **circular reaction** provides a means of adapting first schemes, and the newborn's reflexes gradually transform into the flexible action patterns of the older infant. Eight- to 12-month-olds develop **intentional**, or **goal-directed**, behavior and begin to understand **object permanence**.

© LAURA DWIGHT PHOTOGRAPHY

- Between 18 and 24 months, **mental representation** is evident in sudden solutions to sensorimotor problems, mastery of object permanence problems involving invisible displacement, **deferred imitation**, and **make-believe play**.

#### 5.3 What does follow-up research say about infant cognitive development and the accuracy of Piaget's sensorimotor stage?

- Follow-up research suggests that infants display certain understandings earlier than Piaget believed. Some awareness of object permanence, as revealed by the **violation-of-expectation method** and object-tracking research, may be evident in the first few months. Furthermore, young infants display deferred imitation, and by 10 to 12 months, they can solve problems by analogy—attainments that require mental representation.

- Around their first birthday, babies attain **displaced reference**, the realization that words may stand for things not physically present. By the second year, toddlers treat realistic-looking pictures symbolically. Around 2½ years, the **video deficit effect** declines; children grasp the symbolic meaning of video.
- Researchers believe that newborns have more built-in equipment for making sense of their world than Piaget assumed, although they disagree on how much initial understanding infants have. According to the **core knowledge perspective**, infants are born with core domains of thought, including physical, psychological, linguistic, and numerical knowledge, that support early, rapid cognitive development.
- Broad agreement exists that many cognitive changes of infancy are continuous rather than stagelike and that aspects of cognition develop unevenly rather than in an integrated fashion.

### Information Processing (p. 160)

#### 5.4 Describe the information-processing view of cognitive development and the general structure of the information-processing system.

- Most information-processing researchers assume that we hold information in three parts of the mental system for processing: the **sensory register**, the **short-term memory store**, and **long-term memory**. The **central executive** joins with **working memory**—our “mental workspace”—to process information effectively. **Automatic processes** permit us to focus on other information while performing them.
- Gains in **executive function**—impulse control, flexible thinking, coordinating information in working memory, and planning—in childhood predict important cognitive and social outcomes in adolescence and adulthood.

#### 5.5 What changes in attention, memory, and categorization take place over the first two years?

- With age, infants attend to more aspects of the environment and take information in more quickly. In the second year, attention to novelty declines and sustained attention improves.
- Young infants are capable of **recognition** memory. By the middle of the first year, they also engage in **recall**. Both recognition and recall improve steadily with age.

- Infants group stimuli into an expanding array of categories. In the second year, toddlers begin to categorize flexibly, switching their basis of object sorting, and their grasp of the animate–inanimate distinction expands. Gradually, they shift from a perceptual to a conceptual basis of categorizing.

#### 5.6 Describe the strengths and limitations of the information-processing approach to early cognitive development.

- Information-processing findings challenge Piaget's view of infants as purely sensorimotor beings who cannot mentally represent experiences. But information processing has not yet provided a broad, comprehensive theory of children's thinking.

### The Social Context of Early Cognitive Development (p. 166)

#### 5.7 How does Vygotsky's concept of the zone of proximal development expand our understanding of early cognitive development?

- Vygotsky believed that infants master tasks within the **zone of proximal development**—ones just ahead of their current capacities—through the support and guidance of more skilled partners. As early as the first year, cultural variations in social experiences affect mental strategies.

© JAMES SHAFER/PHOTOFEST

### Individual Differences in Early Mental Development (p. 167)

#### 5.8 Describe the mental testing approach and the extent to which infant tests predict later performance.

- The mental testing approach measures variations in developmental progress in an effort to predict future performance. Scores are arrived at by computing an **intelligence quotient (IQ)**, which compares an individual's test performance with that of a **standardization** sample of same-age individuals, whose scores form a **normal distribution**.

- Infant tests consisting largely of perceptual and motor responses predict later intelligence poorly. As a result, scores on infant tests are called **developmental quotients (DQs)**, rather than IQs. Speed of habituation and recovery to visual stimuli is a better predictor of future performance.

**5.9** *Discuss environmental influences on early mental development, including home, child care, and early intervention for at-risk infants and toddlers.*

- Research with the **Home Observation for Measurement of the Environment (HOME)** shows that an organized, stimulating home environment and parental affection, involvement, and encouragement repeatedly predict higher mental test scores. The extent to which parents talk to infants and toddlers is especially influential.

- Quality of infant and toddler child care influences later cognitive, language, academic, and social skills. Standards for **developmentally appropriate practice** specify program characteristics that meet young children's developmental needs.

- Intensive intervention beginning in infancy and extending through early childhood can prevent the gradual declines in intelligence and the poor academic performance evident in many poverty-stricken children.

**Language Development** (p. 173)

**5.10** *Describe theories of language development, and indicate the emphasis each places on innate abilities and environmental influences.*

- Chomsky's nativist theory regards children as naturally endowed with a **language acquisition device (LAD)**. Consistent with this perspective, mastery of a complex language system is unique to humans, and childhood is a sensitive period for language acquisition.
- Recent theories suggest that language development results from interactions between inner capacities and environmental influences. Some interactionists apply the information-processing perspective to language development. Others emphasize the importance of children's social skills and language experiences.

**5.11** *Describe major language milestones in the first two years, individual differences, and ways adults can support early language development.*

- Infants begin **cooing** at 2 months and **babbling** at about 6 months. Around 10 months, their skill at establishing **joint attention** improves, and soon they use preverbal gestures. Adults can encourage language progress by responding to infants' coos and babbles, playing turn-taking games, establishing joint attention and labeling what babies see, and labeling their preverbal gestures.

- Around 12 months, toddlers say their first word. Young children often make errors of **underextension** and **overextension**. Once vocabulary reaches 200 to 250 words, two-word utterances called **telegraphic speech** appear. At all ages, language comprehension is ahead of production.

- Girls show faster language progress than boys, and reserved toddlers may wait before trying to speak. Most toddlers use a **referential style** of language learning; their early words consist largely of names for objects. Some use an **expressive style**, in which social formulas and pronouns are common and vocabulary grows more slowly.
- Adults in many cultures speak to young children in **infant-directed speech (IDS)**, a simplified form of communication that is well-suited to their learning needs. Parent-toddler conversation is a good predictor of early language development and reading success during the school years. Live interaction with an adult is better suited to spurring language progress than are media sources.

## ■ SOCIAL ISSUES: HEALTH Does Child Care in Infancy Threaten Attachment Security and Later Adjustment?

## ■ CULTURAL INFLUENCES The Role of Fathers' Involvement in Children's Development

## Self-Development

Self-Awareness • Categorizing the Self • Self-Control

As Caitlin reached 8 months of age, her parents noticed that she had become more fearful. One evening, when Carolyn and David left her with a babysitter, she wailed as they headed for the door—an experience she had accepted easily a few weeks earlier. Caitlin and Timmy's caregiver Ginette also observed an increasing wariness of strangers. When she turned to go to another room, both babies dropped their play to crawl after her. At the mail carrier's knock at the door, they clung to Ginette's legs, reaching out to be picked up.

At the same time, each baby seemed more willful. Removing an object from the hand produced little response at 5 months. But at 8 months, when Timmy's mother, Vanessa, took away a table knife he had managed to reach, Timmy burst into angry screams and could not be consoled or distracted.

All Monica and Kevin knew about Grace's first year was that she had been deeply loved by her destitute, homeless mother. Separation from her, followed by a long journey to an unfamiliar home, had left Grace in shock. At first she was extremely sad, turning away when Monica or Kevin picked her up. But as Grace's new parents held her close, spoke gently, and satisfied her craving for food, Grace returned their affection. Two weeks after her arrival, her despondency gave way to a sunny, easygoing disposition. She burst into a wide grin, reached out at the sight of Monica and Kevin, and laughed at her brother Eli's funny faces. As her second birthday approached, she pointed to herself, exclaiming "Gwace!" and laid claim to treasured possessions. "Gwace's chicken!" she would announce at mealtimes, sucking the marrow from the drumstick, a practice she had brought with her from Cambodia.

Taken together, the children's reactions reflect two related aspects of personality development during the first two years: close ties to others and a sense of self. We begin with Erikson's psychosocial theory, which provides an overview of personality development during infancy and toddlerhood. Then, as we chart the course of emotional development, we will discover why fear and anger became more apparent in Caitlin's and Timmy's range of emotions by the end of the first year. Our attention then turns to individual differences in temperament. We will examine genetic and environmental contributions to these differences and their consequences for future development.

Next, we take up attachment to the caregiver, the child's first affectionate tie. We will see how the feelings of security that grow out of this important bond support the child's exploration, self-awareness, and expanding social relationships.

Finally, we focus on early self-development. By the end of toddlerhood, Grace recognized herself in mirrors and photographs, labeled herself as a girl, and showed the beginnings of self-control. "Don't touch!" she instructed herself one day as she resisted the desire to pull a lamp cord out of its socket. Cognitive advances combine with social experiences to produce these changes during the second year. ●

## Erikson's Theory of Infant and Toddler Personality

**6.1** What personality changes take place during Erikson's stages of basic trust versus mistrust and autonomy versus shame and doubt?

Our discussion of major theories in Chapter 1 revealed that the psychoanalytic perspective is no longer in the mainstream of human development research. But one of its lasting contributions is its ability to capture the essence of personality during each period of development. The most influential psychoanalytic approach is Erik Erikson's *psychosocial theory*, summarized on page 15. Let's look closely at his first two stages.

### Basic Trust versus Mistrust

Erikson accepted Freud's emphasis on the importance of the parent–infant relationship during feeding, but he expanded and enriched Freud's view. A healthy outcome during infancy, Erikson believed, does not depend on the *amount* of food or oral stimulation offered but rather on the *quality* of caregiving: relieving discomfort promptly and sensitively, holding the infant gently, waiting patiently until the baby has had enough milk, and weaning when the infant shows less interest in breast or bottle.

Erikson recognized that no parent can be perfectly in tune with the baby's needs. Many factors affect parental responsiveness—personal happiness, family conditions (for example, additional young children, social supports, financial well-being), and culturally valued child-rearing practices. But when the *balance of care* is sympathetic and loving, the psychological conflict of the first year—**basic trust versus mistrust**—is resolved on the positive side. The trusting infant expects the world to be good and gratifying, so he feels confident about venturing out to explore it. The mistrustful baby cannot count on the kindness and compassion of others, so she protects herself by withdrawing from people and things around her.

### Autonomy versus Shame and Doubt

With the transition to toddlerhood, Freud viewed parents' manner of toilet training as decisive for psychological health. In Erikson's view, toilet training is only one of many influential experiences. The familiar refrains of newly walking, talking toddlers—"No!" "Do it myself!"—reveal that they have entered a period of budding selfhood. They want to decide for themselves, not just in toileting but also in other situations. The conflict of toddlerhood, **autonomy versus shame and doubt**, is resolved favorably when parents provide young children with suitable guidance and reasonable choices. A self-confident, secure 2-year-old has parents who do not criticize or attack him when he fails at new skills—using the toilet, eating with a spoon, or putting away toys. And they meet his assertions of independence with tolerance and understanding—for example, by giving him an extra five minutes to finish his play before leaving for the grocery store. In

On a visit to a science museum, a 2-year-old insists on exploring a flight simulator. As the mother supports her toddler's desire to "do it myself," she fosters a healthy sense of autonomy.

contrast, when parents are over- or undercontrolling, the outcome is a child who feels forced and shamed and who doubts his ability to control impulses and act competently on his own.

In sum, basic trust and autonomy grow out of warm, sensitive parenting and reasonable expectations for impulse control starting in the second year. If children emerge from the first few years without sufficient trust in caregivers and without a healthy sense of individuality, the seeds are sown for adjustment problems. Adults who have difficulty establishing intimate ties, who are overly dependent on a loved one, or who continually doubt their own ability to meet new challenges may not have fully mastered the tasks of trust and autonomy during infancy and toddlerhood.

## Emotional Development

**6.2** Describe the development of basic emotions over the first year, noting the adaptive function of each.

**6.3** Summarize changes during the first two years in understanding others' emotions, expression of self-conscious emotions, and emotional self-regulation.

Observe several infants and toddlers, noting the emotions each displays, the cues you rely on to interpret the baby's emotional state, and how caregivers respond. Researchers have conducted many such observations to find out how babies convey their emotions and interpret those of others. They have discovered that emotions play powerful roles in organizing the attainments that Erikson regarded as so important: social relationships, exploration of the environment, and discovery of the self (Saarni et al., 2006).

Think back to the *dynamic systems perspective* introduced in Chapters 1 and 4. As you read about early emotional development in the sections that follow, notice how emotions are an integral part of young children's dynamic systems of action. Emotions energize development. At the same time, they are an aspect of the system that develops, becoming more varied and complex as children reorganize their behavior to attain new goals (Campos, Frankel, & Camras, 2004; Camras, 2011).

Because infants cannot describe their feelings, determining exactly which emotions they are experiencing is a challenge. Cross-cultural evidence reveals that people around the world associate photographs of different facial expressions with emotions in the same way (Ekman & Friesen, 1972; Ekman & Matsumoto, 2011). These findings inspired researchers to analyze infants' facial patterns to determine the range of emotions they display at different ages.

But to express a particular emotion, infants, children, and adults actually use diverse responses—not just facial expressions but also vocalizations and body movements—which vary with their developing capacities, goals, and contexts. Therefore, to infer babies' emotions as accurately as possible, researchers must attend to multiple interacting expressive cues—vocal, facial, and gestural—and see how they vary across situations believed to elicit different emotions (Camras & Shuster, 2013).

## Basic Emotions

**Basic emotions**—happiness, interest, surprise, fear, anger, sadness, and disgust—are universal in humans and other primates and have a long evolutionary history of promoting survival. Do infants come into the world with the ability to express basic emotions?

Although signs of some emotions are present, babies' earliest emotional life consists of little more than two global arousal states: attraction to pleasant stimulation and withdrawal from unpleasant stimulation (Camras et al., 2003). Only gradually do emotions become clear, well-organized signals. The dynamic systems perspective helps us understand how this happens: Children coordinate separate skills into more effective, emotionally expressive systems as the central nervous system develops and the child's goals and experiences change (Camras & Shutter, 2010).

Sensitive, contingent caregiver communication, in which parents selectively mirror aspects of the baby's diffuse emotional behavior, helps infants construct emotional expressions that more closely resemble those of adults (Gergely & Watson, 1999). With age, face, voice, and posture start to form organized patterns that vary meaningfully with environmental events. For example, Caitlin typically responded to her parents' playful interaction with a joyful face, pleasant babbling, and a relaxed posture, as if to say, "This is fun!" In contrast, an unresponsive parent often evokes a sad face, fussy sounds, and a drooping body (sending the message, "I'm despondent") or an angry face, crying, and "pick-me-up" gestures (as if to say, "Change this unpleasant event!") (Weinberg & Tronick, 1994). Gradually,

emotional expressions become well-organized and specific—and therefore provide more precise information about the baby's internal state.

Four basic emotions—happiness, anger, sadness, and fear—have received the most research attention. Let's see how they develop.

**Happiness.** Happiness—expressed first in blissful smiles and later through exuberant laughter—contributes to many aspects of development. When infants achieve new skills, they smile and laugh, displaying delight in motor and cognitive mastery. The baby's smile encourages caregivers to smile responsively and to be affectionate and stimulating, and then the baby smiles even more (Bigelow & Power, 2014). Happiness binds parent and baby into a warm, supportive relationship that fosters the infant's motor, cognitive, and social competencies.

During the early weeks, newborn babies smile when full, during REM sleep, and in response to gentle touches and sounds, such as stroking of the skin, rocking, and a parent's soft, high-pitched voice. By the end of the first month, infants smile at dynamic, eye-catching sights, such as a bright object jumping suddenly across their field of vision. Between 6 and 10 weeks, the parent's communication evokes a broad grin called the **social smile** (Lavelli & Fogel, 2005). These changes parallel the development of infant perceptual capacities—in particular, sensitivity to visual patterns, including the human face (see Chapter 4). Social smiling becomes better-organized and stable as babies learn to use it to evoke and sustain pleasurable face-to-face interaction with their caregivers.

Laughter, which typically appears around 3 to 4 months, reflects faster processing of information than smiling. But as with smiling, the first laughs occur in response to very active stimuli, such as the parent saying playfully, "I'm gonna get you!" and kissing the baby's tummy. As infants understand more about their world, they laugh at events with subtle elements of surprise, such as a silent game of peekaboo. Soon they pick up on parents' facial and vocal cues to humor (Mireault et al., 2015). From 5 to 7 months, in the presence of those cues, they increasingly find absurd events—such as an adult wearing a ball as a clown's nose—funny.

During the second half-year, babies smile and laugh more when interacting with familiar people, a preference that strengthens the parent-child bond. And like adults, 10- to 12-month-olds have several smiles, which vary with context—a broad, "cheek-raised" smile in response to a parent's greeting; a reserved, muted smile for a friendly stranger; and a "mouth-open" smile during stimulating play (Messinger & Fogel, 2007). By the end of the first year, the smile has become a deliberate social signal.

**Anger and Sadness.** Newborn babies respond with generalized distress to a variety of unpleasant experiences, including hunger, painful medical procedures, changes in body temperature, and too much or too little stimulation. From 4 to 6 months into the second year, angry expressions increase in frequency and intensity (Braungart-Rieker, Hill-Soderlund, & Karrass,

2010). Older infants also react with anger in a wider range of situations—when an interesting object or event is removed, an expected pleasant event does not occur, their arms are restrained, the caregiver leaves for a brief time, or they are put down for a nap (Camras et al., 1992; Stenberg & Campos, 1990; Sullivan & Lewis, 2003).

Why do angry reactions increase with age? As infants become capable of intentional behavior (see Chapter 5), they want to control their own actions and the effects they produce (Mascolo & Fischer, 2007). Furthermore, older infants are better at identifying who caused them pain or removed a toy. Their anger is particularly intense when a caregiver from whom they have come to expect warm behavior causes discomfort. And increased parental limit setting once babies crawl and walk contributes to babies' angry responses (Roben et al., 2012). The rise in anger is also adaptive. Independent movement enables an angry infant to defend herself or overcome an obstacle to obtain a desired object. Finally, anger motivates caregivers to relieve the baby's distress and, in the case of separation, may discourage them from leaving again soon.

Although expressions of sadness also occur in response to pain, removal of an object, and brief separations, they are less frequent than anger (Alessandri, Sullivan, & Lewis, 1990). But when caregiver–infant communication is seriously disrupted, infant sadness is common—a condition that impairs all aspects of development (see the Biology and Environment box on the following page).

**Fear.** Like anger, fear rises from the second half of the first year into the second year (Braungart-Rieker, Hill-Soderlund, & Karrass, 2010; Brooker et al., 2013). Older infants hesitate before playing with a new toy, and newly crawling infants soon back away from heights (see Chapter 4). But the most frequent expression of fear is to unfamiliar adults, a response called **stranger anxiety**. Many infants and toddlers are quite wary of strangers, although the reaction does not always occur. It depends on several factors: temperament (some babies are generally more fearful), past experiences with strangers, and the current situation. When an unfamiliar adult picks up the infant in a new setting, stranger anxiety is likely. But if the adult sits still while the baby moves around and a parent is nearby, infants often show positive and curious behavior (Horner, 1980). The stranger's style of interaction—expressing warmth, holding out an attractive toy, playing a familiar game, and approaching slowly rather than abruptly—reduces the baby's fear.

### LOOK and LISTEN

While observing an 8- to 18-month-old with his or her parent, gently approach the baby, offering a toy. Does the baby respond with stranger anxiety? To better understand the baby's behavior, ask the parent to describe his or her temperament and past experiences with strangers.

© DAVID EDWARDS/NATIONAL GEOGRAPHIC/GETTY IMAGES

Stranger anxiety appears in many infants after 6 months of age. This baby, though safe in her mother's arms, observes her doctor with cautious curiosity.

Cross-cultural research reveals that infant-rearing practices can modify stranger anxiety. Among the Efe hunters and gatherers of the Republic of Congo, where the maternal death rate is high, infant survival is safeguarded by a collective caregiving system in which, starting at birth, Efe babies are passed from one adult to another. Consequently, Efe infants show little stranger anxiety (Tronick, Morelli, & Ivey, 1992). In contrast, among infants in Israeli kibbutzim (cooperative agricultural settlements), who live in isolated communities vulnerable to terrorist attacks, wariness of strangers is widespread. By the end of the first year, when infants look to others for cues about how to respond emotionally, kibbutz babies display greater stranger anxiety than their city-reared counterparts (Saarni et al., 2006).

The rise in fear after age 6 months keeps newly mobile babies' enthusiasm for exploration in check. Once wariness develops, infants use the familiar caregiver as a **secure base**, or point from which to explore, venturing into the environment and then returning for emotional support. As part of this adaptive system, encounters with strangers lead to two conflicting tendencies: approach (indicated by interest and friendliness) and avoidance (indicated by fear). The infant's behavior is a balance between the two.

As cognitive development enables toddlers to discriminate more effectively between threatening and nonthreatening people and situations, stranger anxiety and other fears of the first two years decline. Fear also wanes as toddlers acquire more strategies for coping with it, as we will see when we discuss emotional self-regulation.

## Biology and Environment

### Parental Depression and Child Development

About 8 to 10 percent of women experience chronic depression—mild to severe feelings of sadness, distress, and withdrawal that continue for months or years. Often, the beginnings of this emotional state cannot be pinpointed. In other instances, depression emerges or strengthens after childbirth but fails to subside as the new mother adjusts to hormonal changes in her body and gains confidence in caring for her baby. This is called *postpartum depression*.

Although it is less recognized and studied, fathers, too, experience chronic depression. About 3 to 5 percent of fathers report symptoms after the birth of a child (Thombs, Roseman, & Arthurs, 2010). Parental depression can interfere with effective parenting and seriously impair children's development. Genetic makeup increases the risk of depressive illness, but social and cultural factors are also involved.

#### Maternal Depression

During Julia's pregnancy, her husband, Kyle, showed so little interest in the baby that Julia worried that having a child might be a mistake. Then, shortly after Lucy was born, Julia's mood plunged. She felt anxious and weepy, overwhelmed by Lucy's needs, and angry at loss of control over her own schedule. When Julia approached Kyle about her own fatigue and his unwillingness to help with the baby, he snapped that she was overreacting. Julia's childless friends stopped by just once to see Lucy but did not call again.

Julia's depressed mood quickly affected her baby. In the weeks after birth, infants of depressed mothers sleep poorly, are less attentive to their surroundings, and have elevated levels of the stress hormone cortisol (Fernandes et al., 2015; Goodman et al., 2011; Natsuaki et al., 2014). The more extreme the depression and the greater the number of stressors in a mother's life (such as marital discord, little or no social support, and poverty), the more the parent-child relationship suffers. Julia rarely smiled at, comforted, or talked to Lucy, who responded to her mother's sad, vacant gaze by turning away, crying, and often looking sad or angry herself (Field, 2011;

Vaeber et al., 2015). By age 6 months, Lucy showed symptoms common in babies of depressed mothers—delays in motor and cognitive development, poor emotion regulation, an irritable mood, and attachment difficulties—outcomes that, without intervention, usually persist (Ibanez et al., 2015; Lefkovic, Baji, & Rigó, 2014; Vedova, 2014).

Depressed mothers view their babies negatively, which contributes to their inept caregiving (Lee & Hans, 2015). As their children get older, these mothers' lack of warmth and involvement is often accompanied by inconsistent discipline—sometimes lax, at other times too forceful (Thomas et al., 2015). As we will see in later chapters, children who experience these maladaptive parenting practices often have serious adjustment problems. Some withdraw into a depressive mood themselves; others become impulsive and aggressive. In one study, children born to mothers who were depressed during pregnancy were four times as likely as children of nondepressed mothers to have engaged in violent antisocial behavior by age 16, after other stressors in the mother's life that could contribute to youth antisocial conduct had been controlled (Hay et al., 2010).

#### Paternal Depression

In a study of a large representative sample of British parents and babies, researchers assessed depressive symptoms of fathers shortly after birth and again the following year. Then they tracked the children's development into the preschool years (Ramchandani et al., 2008). Persistent paternal depression was, like maternal depression, a strong predictor of child behavior problems—especially overactivity, defiance, and aggression in boys.

Paternal depression is linked to frequent marital and father-child conflict as children grow older (Gutierrez-Galve et al., 2015; Kane & Garber, 2004). Over time, children subjected to parental negativity develop a pessimistic world view—one in which they lack self-confidence and perceive their parents and other people as threatening. Children who constantly feel in danger are especially likely

This father appears disengaged from his son. Disruptions in the parent-child relationship caused by paternal depression often lead to serious child behavior problems.

© CATCHLIGHT VISUAL SERVICES/ALAMY STOCK PHOTO

to become overly aroused in stressful situations, easily losing control in the face of cognitive and social challenges (Sturge-Apple et al., 2008). Although children of depressed parents may inherit a tendency toward emotional and behavior problems, quality of parenting is a major factor in their adjustment.

#### Interventions

Early treatment is vital to prevent parental depression from interfering with the parent-child relationship. Julia's doctor referred her to a therapist, who helped Julia and Kyle with their marital problems. At times, antidepressant medication is prescribed.

In addition to alleviating parental depression, therapy that encourages depressed parents to revise negative views of their babies and to engage in emotionally positive, responsive caregiving is vital for reducing attachment and other developmental problems (Goodman et al., 2015). When a depressed parent does not respond easily to treatment, a warm relationship with the other parent or another caregiver can safeguard children's development.

## Understanding and Responding to the Emotions of Others

Infants' emotional expressions are closely tied to their ability to interpret the emotional cues of others. We have seen that in the first few months, babies match the feeling tone of the caregiver in face-to-face communication. Around 3 months, they become sensitive to the structure and timing of face-to-face interactions (see Chapter 5, page 176). When they gaze, smile, or vocalize, they now expect their social partner to respond in kind, and they reply with positive vocal and emotional reactions (Bigelow & Power, 2014; Markova & Legerstee, 2006). Within these exchanges, infants become increasingly aware of the range of emotional expressions (Montague & Walker-Andrews, 2001). Recall from Chapter 4 (page 133) that according to some researchers, out of this early imitative communication, they start to view others as “like me”—an awareness believed to lay the foundation for understanding others' thoughts and feelings (Meltzoff, 2013).

By 4 to 5 months, infants distinguish positive from negative emotion in voices, and soon after, in facial expressions, gradually discriminating a wider range of emotions (see Chapter 4). Responding to emotional expressions as organized wholes indicates that these signals are becoming meaningful to babies. As skill at establishing joint attention improves, infants realize that an emotional expression not only has meaning but is also a meaningful reaction to a specific object or event (Thompson, 2015).

Once these understandings are in place, beginning at 8 to 10 months, infants engage in **social referencing**—actively seeking emotional information from a trusted person in an uncertain situation (Mumme et al., 2007). Many studies show that the caregiver's emotional expression (happy, angry, or fearful) influences whether a 1-year-old will be wary of strangers, play with an unfamiliar toy, or cross the deep side of the visual cliff (see page 140) (de Rosnay et al., 2006; Stenberg, 2003; Striano & Rochat, 2000). The adult's voice—either alone or combined with a facial expression—is more effective than a facial expression alone (Kim, Walden, & Knieps, 2010; Vaish & Striano, 2004). The voice conveys both emotional and verbal information, and the baby need not turn toward the adult but, instead, can focus on evaluating the novel event.

As toddlers start to appreciate that others' emotional reactions may differ from their own, social referencing allows them to compare their own and others' assessments of events. In one study, an adult showed 14- and 18-month-olds broccoli and crackers and acted delighted with one food but disgusted with the other. When asked to share the food, 18-month-olds offered the adult whichever food she appeared to like, regardless of their own preferences (Repacholi & Gopnik, 1997).

In sum, in social referencing, toddlers use others' emotional messages to evaluate the safety and security of their surroundings, to guide their own actions, and to gather information about others' intentions and preferences. These experiences, along with cognitive and language development, probably help toddlers refine the meanings of emotions—for example, happiness versus

surprise, anger versus fear—during the second year (Gendler, Witherington, & Edwards, 2008).

## Emergence of Self-Conscious Emotions

Besides basic emotions, humans are capable of a second, higher-order set of feelings, including guilt, shame, embarrassment, envy, and pride. These are called **self-conscious emotions** because each involves injury to or enhancement of our sense of self. We feel guilt when we have harmed someone and want to correct the wrongdoing. Envy arises when we desire something that another possesses, so we try to restore our sense of self-worth by securing that possession. When we are ashamed or embarrassed, we have negative feelings about our behavior, and we want to retreat so others will no longer notice our failings. In contrast, pride reflects delight in the self's achievements, and we are inclined to tell others what we have accomplished and to take on further challenges (Lewis, 2014).

Self-conscious emotions appear in the middle of the second year, as 18- to 24-month-olds become firmly aware of the self as a separate, unique individual. Toddlers show shame and embarrassment by lowering their eyes, hanging their head, and hiding their face with their hands. They show guiltlike reactions, too. After noticing Grace's unhappiness, 22-month-old Caitlin returned a toy she had grabbed and patted her upset playmate. Pride and envy also emerge around age 2 (Barrett, 2005; Garner, 2003; Lewis, 2014).

© LAURA DWIGHT PHOTOGRAPHY

This 2-year-old's older sister praises his success at tower building. To experience self-conscious emotions, such as pride, young children need self-awareness as well as instruction in when to feel proud of an accomplishment.

Besides self-awareness, self-conscious emotions require an additional ingredient: adult instruction in *when* to feel proud, ashamed, or guilty. Parents begin this tutoring early when they say, “Look how far you can throw that ball!” or “You should feel ashamed for grabbing that toy!” Self-conscious emotions play important roles in children’s achievement-related and moral behaviors. The situations in which adults encourage these feelings vary from culture to culture. In Western nations, most children are taught to feel pride in personal achievement—throwing a ball the farthest, winning a game, and (later on) getting good grades. In cultures such as China and Japan, which promote an interdependent self, calling attention to individual success evokes embarrassment and self-effacement. And violating cultural standards by failing to show concern for others—a parent, a teacher, or an employer—sparks intense shame (Lewis, 2014).

## Beginnings of Emotional Self-Regulation

Besides expressing a wider range of emotions, infants and toddlers begin to manage their emotional experiences. **Emotional self-regulation** refers to the strategies we use to adjust our emotional state to a comfortable level of intensity so we can accomplish our goals (Eisenberg, 2006; Thompson & Goodvin, 2007). When you remind yourself that an anxiety-provoking event will be over soon, suppress your anger at a friend’s behavior, or decide not to see a scary horror film, you are engaging in emotional self-regulation.

Emotional self-regulation requires voluntary, effortful management of emotions. It improves rapidly during the first few years, as the result of a *dynamic system* of influences that include development of the prefrontal cortex and its networks of connections to brain areas involved in emotional reactivity and control; and support from caregivers, who help children manage intense emotion and, as cognitive and language skills improve, teach them strategies for doing so on their own (Rothbart, Posner, & Kieras, 2006; Thompson, 2015). Individual differences in control of emotion are evident in infancy and, by early childhood, play such a vital role in adjustment that—as we will see later—they are viewed as a major dimension of temperament, called *effortful control*.

In the early months, infants have only a limited capacity to regulate their emotional states. When their feelings get too intense, they are easily overwhelmed. They depend on soothing interventions of caregivers—being lifted to the shoulder, rocked, gently stroked, and talked to softly—for distraction and reorienting of attention.

More effective functioning of the prefrontal cortex increases the baby’s tolerance for stimulation. Between 2 and 4 months, caregivers build on this capacity by initiating face-to-face play and attention to objects. In these interactions, parents arouse pleasure in the baby while adjusting the pace of their behavior so the infant does not become overwhelmed and distressed (Kopp & Neufeld, 2003). As a result, the baby’s tolerance for stimulation increases further.

From 3 months on, the ability to shift attention helps infants control emotion. Babies who more readily turn away from unpleasant events or engage in self-soothing are less prone to distress (Ekas, Lickenbrock, & Braungart-Rieker, 2013). And crawling and walking, which permit babies to approach or retreat from various situations, foster more effective self-regulation.

Infants whose parents “read” and respond contingently and sympathetically to their emotional cues tend to be less fussy and fearful, to express more pleasurable emotion, to be more interested in exploration, and to be easier to soothe (Braungart-Rieker, Hill-Soderlund, & Karrass, 2010; Crockenberg & Leerkes, 2004). In contrast, parents who respond impatiently or angrily or who wait to intervene until the infant has become extremely agitated reinforce the baby’s rapid rise to intense distress. When caregivers fail to regulate stressful experiences for infants who cannot yet regulate such experiences for themselves, brain structures that buffer stress may fail to develop properly, resulting in an anxious, reactive child who has a reduced capacity for managing emotional problems (Blair & Raver, 2012; Frankel et al., 2015).

Caregivers also provide lessons in socially approved ways of expressing feelings. Beginning in the first few months, parents encourage infants to suppress negative emotion by imitating their expressions of interest, happiness, and surprise more often than their expressions of anger and sadness. Boys get more of this training than girls, in part because boys have a harder time regulating negative emotion (Else-Quest et al., 2006; Malatesta et al., 1986). As a result, the well-known sex difference—females as emotionally expressive and males as emotionally controlled—is promoted at a tender age.

Cultures that highly value social harmony place particular emphasis on socially appropriate emotional behavior while discouraging expression of individual feelings. Compared with Western parents, Japanese and Chinese parents, and parents in many non-Western village cultures, discourage the expression of strong emotion in babies. Nso mothers of rural Cameroon, for example, spend less time imitating infant social smiling than do German mothers, and Nso mothers are especially quick to anticipate and quiet infant distress through soothing and breastfeeding. Chinese, Japanese, and Nso babies, in turn, smile, laugh, and cry less than their Western agemates (Friedlmeier, Corapci, & Cole, 2011; Gartstein et al., 2010; Kärtner, Holodyski, & Wörmann, 2013).

Toward the end of the second year, a vocabulary for talking about feelings—“happy,” “love,” “surprised,” “scary,” “yucky,” “mad”—develops rapidly, but toddlers are not yet good at using language to manage their emotions. Temper tantrums tend to occur because toddlers cannot control the intense anger that often arises when an adult rejects their demands, particularly when they are fatigued or hungry (Mascolo & Fischer, 2007). Toddlers whose parents are emotionally sympathetic but set limits (by not giving in to tantrums), who distract the child by offering acceptable alternatives, and who later suggest better ways to handle adult refusals display more effective anger-regulation strategies and social skills during the preschool years (LeCuyer & Houck, 2006).

Patient, sensitive parents also encourage toddlers to describe their internal states. Then, when 2-year-olds feel distressed, they can guide caregivers in helping them (Cole, Armstrong, & Pemberton, 2010). For example, while listening to a story about monsters, Grace whimpered, “Mommy, scary.” Monica put the book down and gave Grace a comforting hug.

## Ask yourself

**CONNECT** Why do children of depressed parents have difficulty regulating emotion (see page 187)? What implications do their weak self-regulatory skills have for their response to cognitive and social challenges?

**APPLY** At age 14 months, Reggie built a block tower and gleefully knocked it down. At age 2, he called to his mother and pointed proudly to his tall block tower. What explains this change in Reggie’s emotional behavior?

**REFLECT** Describe several recent instances illustrating how you typically manage negative emotion. How might your early experiences, gender, and cultural background have influenced your style of emotional self-regulation?

## Temperament and Development

**6.4** What is temperament, and how is it measured?

**6.5** Discuss the roles of heredity and environment in the stability of temperament, including the goodness-of-fit model.

From early infancy, Caitlin’s sociability was unmistakable. She smiled and laughed while interacting with adults and, in her second year, readily approached other children. Meanwhile, Monica marveled at Grace’s calm, relaxed disposition. At 19 months, she sat contentedly in a highchair through a two-hour family celebration at a restaurant. In contrast, Timmy was active and distractible. Vanessa found herself chasing him as he dropped one toy, moved on to the next, and climbed on chairs and tables.

When we describe one person as cheerful and “upbeat,” another as active and energetic, and still others as calm, cautious, or prone to angry outbursts, we are referring to **temperament**—early-appearing, stable individual differences in reactivity and self-regulation. *Reactivity* refers to quickness and intensity of emotional arousal, attention, and motor activity. *Self-regulation*, as we have seen, refers to strategies that modify that reactivity (Rothbart, 2011; Rothbart & Bates, 2006). The psychological traits that make up temperament are believed to form the cornerstone of the adult personality.

In 1956, Alexander Thomas and Stella Chess initiated the New York Longitudinal Study, a groundbreaking investigation of the development of temperament that followed 141 children from early infancy well into adulthood. Results showed that tempera-

ment can increase a child’s chances of experiencing psychological problems or, alternatively, protect a child from the negative effects of a highly stressful home life. At the same time, Thomas and Chess (1977) discovered that parenting practices can modify children’s temperaments considerably.

These findings stimulated a growing body of research on temperament, including its stability, biological roots, and interaction with child-rearing experiences. Let’s begin to explore these issues by looking at the structure, or makeup, of temperament and how it is measured.

## The Structure of Temperament

Thomas and Chess’s model of temperament inspired all others that followed. When detailed descriptions of infants’ and children’s behavior obtained from parent interviews were rated on nine dimensions of temperament, certain characteristics clustered together, yielding three types of children:

- The **easy child** (40 percent of the sample) quickly establishes regular routines in infancy, is generally cheerful, and adapts easily to new experiences.
- The **difficult child** (10 percent of the sample) is irregular in daily routines, is slow to accept new experiences, and tends to react negatively and intensely.
- The **slow-to-warm-up child** (15 percent of the sample) is inactive, shows mild, low-key reactions to environmental stimuli, is negative in mood, and adjusts slowly to new experiences.

Note that 35 percent of the children did not fit any of these categories. Instead, they showed unique blends of temperamental characteristics.

The difficult pattern has sparked the most interest because it places children at high risk for adjustment problems—both anxious withdrawal and aggressive behavior in early and middle childhood (Bates, Wachs, & Emde, 1994; Ramos et al., 2005). Nevertheless, the difficult label has been criticized because judgments of child difficulty vary widely across caregivers and cultures. Compared with difficult children, slow-to-warm-up children present fewer problems in the early years. However, they tend to show excessive fearfulness and slow, constricted behavior in the late preschool and school years, when they are expected to respond actively and quickly in classrooms and peer groups (Chess & Thomas, 1984; Schmitz et al., 1999).

Today, the most influential model of temperament is Mary Rothbart’s, described in Table 6.1. It combines related traits proposed by Thomas and Chess and other researchers, yielding a concise list of just six dimensions. For example, distractibility and persistence are considered opposite ends of the same dimension, which is labeled “attention span/persistence.” A unique feature of Rothbart’s model is inclusion of both “fearful distress” and “irritable distress,” which distinguish between reactivity triggered by fear and reactivity due to frustration. And the model deletes overly broad dimensions such as regularity of body

**TABLE 6.1**  
**Rothbart's Model of Temperament**

DIMENSION	DESCRIPTION
<b>REACTIVITY</b>	
Activity level	Level of gross-motor activity
Attention span/persistence	Duration of orienting or interest
Fearful distress	Wariness and distress in response to intense or novel stimuli, including time to adjust to new situations
Irritable distress	Extent of fussing, crying, and distress when desires are frustrated
Positive affect	Frequency of expression of happiness and pleasure
<b>SELF-REGULATION</b>	
Effortful control	Capacity to voluntarily suppress a dominant, reactive response in order to plan and execute a more adaptive response  In the first two years, called <i>orienting/regulation</i> , which refers to the capacity to engage in self-soothing, shift attention from unpleasant events, and sustain interest for an extended time

functions and intensity of reaction (Rothbart, 2011; Rothbart, Ahadi, & Evans, 2000). A child who is regular in sleeping is not necessarily regular in eating or bowel habits. And a child who smiles and laughs intensely is not necessarily intense in fear, irritability, or motor activity.

Rothbart's dimensions represent the three underlying components included in the definition of temperament: (1) *emotion* ("fearful distress," "irritable distress," "positive affect"), (2) *attention* ("attention span/persistence"), and (3) *action* ("activity level"). Individuals differ not just in their reactivity on each dimension but also in the self-regulatory dimension of temperament, **effortful control**—the capacity to voluntarily suppress a dominant response in order to plan and execute a more adaptive response (Rothbart, 2003; Rothbart & Bates, 2006). Variations in effortful control are evident in how effectively a child can focus and shift attention, inhibit impulses, and manage negative emotion.

The capacity for effortful control in early childhood predicts favorable development and adjustment in cultures as diverse as China and the United States, with some studies showing long-term effects into adolescence and adulthood (Chen & Schmidt, 2015). Positive outcomes include persistence, task mastery, academic achievement, cooperation, moral maturity (such as concern about wrongdoing and willingness to apologize), and social behaviors of cooperation, sharing, and helpfulness (Eisenberg, 2010; Kochanska & Aksan, 2006; Posner & Rothbart, 2007;

Valiente, Lemery-Chalfant, & Swanson, 2010). Effortful control is also associated with children's resistance to stress (David & Murphy, 2007). Children high in effortful control are better able to shift attention away from disturbing events and their own anxiety to more positive features of their social environments.

Turn back to page 161 in Chapter 5 to review the concept of executive function, and note its resemblance to effortful control. These converging concepts, which are associated with similar positive outcomes, reveal that the same mental activities lead to effective regulation in both the cognitive and emotional/social domains.

## Measuring Temperament

Temperament is often assessed through interviews or questionnaires given to parents. Behavior ratings by pediatricians, teachers, and others familiar with the child and laboratory observations by researchers have also been used. Parental reports are convenient and take advantage of parents' depth of knowledge about their child across many situations (Chen & Schmidt, 2015). Although information from parents has been criticized as being biased, parental reports are moderately related to researchers' observations of children's behavior (Majdandžić & van den Boom, 2007; Mangelsdorf, Schoppe, & Buur, 2000). And parent perceptions are useful for understanding how parents view and respond to their child.

Observations by researchers in the home or laboratory avoid the subjectivity of parental reports but can lead to other inaccuracies. In homes, observers find it hard to capture rare but important events, such as infants' response to frustration. And in the unfamiliar lab setting, fearful children who calmly avoid certain experiences at home may become too upset to complete the session (Rothbart, 2011). Still, researchers can better control children's experiences in the lab. And they can conveniently combine observations of behavior with neurobiological measures to gain insight into the biological bases of temperament.

Most neurobiological research has focused on children who fall at opposite extremes of the positive-affect and fearful-distress dimensions of temperament: **inhibited**, or **shy, children**, who react negatively to and withdraw from novel stimuli, and **uninhibited**, or **sociable, children**, who display positive emotion to and approach novel stimuli. As the Biology and Environment box on page 192 reveals, biologically based reactivity—evident in heart rate, hormone levels, and measures of brain activity—differentiates children with inhibited and uninhibited temperaments.

## Stability of Temperament

Young children who score low or high on attention span, irritability, sociability, shyness, or effortful control tend to respond similarly when assessed again several months to a few years later and, occasionally, even into the adult years (Casalin et al., 2012; Caspi et al., 2003; Kochanska & Knaack, 2003; Majdandžić &

## Biology and Environment

### Development of Shyness and Sociability

Two 4-month-old babies, Larry and Mitch, visited the laboratory of Jerome Kagan, who observed their reactions to a variety of unfamiliar experiences. When exposed to new sights and sounds, such as a moving mobile decorated with colorful toys, Larry tensed his muscles, moved his arms and legs with agitation, and began to cry. In contrast, Mitch remained relaxed and quiet, smiling and cooing.

As toddlers, Larry and Mitch returned to the laboratory, where they experienced several procedures designed to induce uncertainty. Electrodes were placed on their bodies and blood pressure cuffs on their arms to measure heart rate; toy robots, animals, and puppets moved before their eyes; and unfamiliar people behaved in unexpected ways or wore novel costumes. While Larry whimpered and quickly withdrew, Mitch watched with interest, laughed, and approached the toys and strangers.

On a third visit, at age 4½, Larry barely talked or smiled during an interview with an unfamiliar adult. In contrast, Mitch asked questions and communicated his pleasure at each new activity. In a playroom with two unfamiliar peers, Larry pulled back and watched, while Mitch made friends quickly.

In longitudinal research on several hundred European-American infants followed into adolescence, Kagan found that about 20 percent of 4-month-olds were, like Larry, easily upset by novelty; another 40 percent, like Mitch, were comfortable, even delighted, with new experiences. About 20 to 25 percent of these extreme groups retained their temperamental styles as they grew older (Kagan, 2003, 2013d; Kagan et al., 2007). But most children's dispositions became less extreme over time. Genetic makeup and child-rearing experiences jointly influenced stability and change in temperament.

#### Neurobiological Correlates of Shyness and Sociability

Individual differences in arousal of the *amygdala*, an inner brain structure devoted to processing novelty and emotional informa-

tion, contribute to these contrasting temperaments. In shy, inhibited children, novel stimuli easily excite the amygdala and its connections to the prefrontal cortex and the sympathetic nervous system, which prepares the body to act in the face of threat. In sociable, uninhibited children, the same level of stimulation evokes minimal neural excitation (Schwartz et al., 2012). And additional neurobiological responses known to be mediated by the amygdala distinguish these two emotional styles:

- **Heart rate.** From the first few weeks of life, the heart rates of shy children are consistently higher than those of sociable children, and they speed up further in response to unfamiliar events (Schmidt et al., 2007; Snidman et al., 1995).
- **Cortisol.** Saliva concentrations of the stress hormone cortisol tend to be higher, and to rise more in response to a stressful event, in shy than in sociable children (Schmidt et al., 1999; Zimmermann & Stansbury, 2004).
- **Pupil dilation, blood pressure, and skin surface temperature.** Compared with sociable children, shy children show greater pupil dilation, rise in blood pressure, and cooling of the fingertips when faced with novelty (Kagan et al., 2007).

Furthermore, shy infants and preschoolers show greater EEG activity in the right than in the left frontal lobe of the cerebral cortex, which is associated with negative emotional reactivity; sociable children show the opposite pattern (Fox et al., 2008). Neural activity in the amygdala, which is transmitted to the frontal lobes, probably contributes to these differences.

#### Child-Rearing Practices

According to Kagan, most extremely shy or sociable children inherit a physiology that biases them toward a particular temperamental style (Kagan, 2013d). Yet heritability research indicates that genes contribute only modestly to shyness and sociability.

Child-rearing practices affect the chances that an emotionally reactive baby will become

© LAURA DWIGHT PHOTOGRAPHY

A strong physiological response to uncertain situations prompts this toddler to cling to her father. With patient but insistent encouragement, her parents can help her overcome the urge to retreat.

a fearful child. Warm, supportive parenting reduces shy infants' and preschoolers' intense physiological reactivity to novelty, whereas cold, intrusive parenting heightens anxiety (Coplan & Arbeau, 2008; Davis & Buss, 2012). And if parents overprotect infants and young children who dislike novelty, they make it harder for the child to overcome an urge to retreat. Parents who make appropriate demands for their child to approach new experiences help shy youngsters develop strategies for regulating fear (Rubin & Burgess, 2002).

When inhibition persists, it leads to excessive cautiousness, low self-esteem, and loneliness. In adolescence, persistent shyness increases the risk of severe anxiety, depression, and other internalizing problems, including unrealistic worries about harm, illness, and criticism for mistakes as well as social phobia—intense fear of being humiliated in social situations (Kagan, 2013d; Karevold et al., 2012). For inhibited children to acquire effective social skills, parenting must be tailored to their temperaments—a theme we will encounter again in this and later chapters.

van den Boom, 2007; van den Akker et al., 2010). However, the overall stability of temperament is low in infancy and toddlerhood and only moderate from the preschool years on (Putnam, Sanson, & Rothbart, 2000).

Why isn't temperament more stable? A major reason is that temperament itself develops with age. To illustrate, let's look at irritability and activity level. Recall from Chapter 3 that the early months are a period of fussing and crying for most babies. As infants better regulate their attention and emotions, many who initially seemed irritable become calm and content. With respect to activity level, the meaning of the behavior changes. At first, an active, wriggling infant tends to be highly aroused and uncomfortable, whereas an inactive baby is often alert and attentive. Once infants move on their own, the reverse is so! An active crawler is usually alert and interested in exploration, whereas an inactive baby may be fearful and withdrawn.

These discrepancies help us understand why long-term prediction from early temperament is best achieved after age 3, when children's styles of responding are better established (Roberts & DelVecchio, 2000). In line with this idea, between age 2½ and 3, children improve substantially and also perform more consistently across a wide range of tasks requiring effortful control, such as waiting for a reward, lowering their voice to a whisper, succeeding at games like "Simon Says," and selectively attending to one stimulus while ignoring competing stimuli (Kochanska, Murray, & Harlan, 2000; Li-Grining, 2007). Researchers believe that around this time, areas in the prefrontal cortex involved in suppressing impulses develop rapidly (Rothbart, 2011).

Nevertheless, the ease with which children manage their reactivity in early childhood depends on the type and strength of the reactive emotion involved. Compared to angry, irritable toddlers, fearful toddlers generally show greater improvement in effortful control by the preschool years (Bridgett et al., 2009; Kochanska & Knaack, 2003). Child rearing is also important in modifying reactivity. Young children with either fearful or irritable temperaments who experience patient, supportive parenting gain most in capacity to manage their emotions (Kim & Kochanska, 2012; Warren & Simmens, 2005). But if exposed to insensitive or unresponsive parenting, these emotionally negative children are especially likely to score low in effortful control, placing them at high risk for adjustment problems.

In sum, many factors affect the extent to which a child's temperament remains stable, including development of the biological systems on which temperament is based, the child's capacity for effortful control, and the success of her efforts, which depend on the quality and intensity of her emotional reactivity. When we consider the evidence as a whole, the low to moderate stability of temperament makes sense. It also confirms that child rearing can modify biologically based temperamental traits considerably and that children with certain traits, such as negative emotionality, are especially susceptible to the influence of parenting—a finding we will return to shortly. With these ideas in mind, let's turn to genetic and environmental contributions to temperament and personality.

## Genetic and Environmental Influences

The word *temperament* implies a genetic foundation for individual differences in personality. Identical twins are more similar than fraternal twins across a wide range of temperamental and personality traits (Caspi & Shiner, 2006; Krueger & Johnson, 2008; Roisman & Fraley, 2006). In Chapter 2, we noted that heritability estimates derived from twin studies suggest a moderate role for genetic factors in temperament and personality: About half of individual differences have been attributed to differences in genetic makeup.

Although genetic influences on temperament are clear, environment is also powerful. Recall from Chapter 4 that children exposed to severe malnutrition in infancy remain more distractible and fearful than their agetates, even after dietary improvement. And infants reared in deprived orphanages are easily overwhelmed by stressful events. Their poor regulation of emotion results in inattention and weak impulse control, including frequent expressions of anger (see page 123).

Furthermore, heredity and environment often jointly contribute to temperament, since a child's approach to the world can be intensified or lessened by experience. To illustrate, let's begin by looking at ethnic and gender differences.

**Ethnic and Gender Differences.** Compared with European-American infants, Chinese and Japanese babies tend to be less active, irritable, vocal, more easily soothed when upset, and better at quieting themselves (Kagan, 2013d; Lewis, Ramsay, & Kawakami, 1993). East Asian babies are also more attentive and less distractible, and as 2-year-olds, they are more compliant and cooperative with adults and higher in effortful control—for example, able to wait longer to play with an attractive toy (Chen et al., 2003; Gartstein et al., 2006). At the same time, Chinese and Japanese babies are more fearful, remaining closer to their mothers in an unfamiliar playroom and displaying more anxiety when interacting with a stranger (Chen, Wang, & DeSouza, 2006).

These variations may have genetic roots, but they are supported by cultural beliefs and practices, yielding *gene-environment correlations* (see pages 68–69 in Chapter 2). Japanese mothers usually say that babies come into the world as independent beings who must learn to rely on their parents through close physical contact. European-American mothers, in contrast, typically believe that they must wean the baby away from dependency toward autonomy. Consistent with these beliefs, Asian mothers interact gently, soothingly, and gesturally with their babies, whereas European-American mothers use a more active, stimulating, verbal approach (Kagan, 2010). Also, recall from our discussion of emotional self-regulation that Chinese and Japanese adults discourage babies from expressing strong emotion, which contributes further to their infants' tranquility.

Similarly, gender differences in temperament are evident as early as infancy, suggesting a genetic foundation. Boys tend to be more active and daring, less fearful, more irritable when

frustrated, more likely to express high-intensity pleasure in play, and more impulsive than girls—factors that contribute to boys' higher injury rates throughout childhood and adolescence. And girls' large advantage in effortful control undoubtedly contributes to their greater compliance and cooperativeness, better school performance, and lower incidence of behavior problems (Else-Quest, 2012; Olino et al., 2013). At the same time, parents more often encourage their young sons to be physically active and their daughters to seek help and physical closeness—through activities they encourage and through more positive reactions when their child exhibits temperamental traits consistent with gender stereotypes (Bryan & Dix, 2009; Hines, 2015). Perhaps for this reason, gender differences in some temperamental traits widen by adolescence.

### Differential Susceptibility to Rearing Experiences.

Earlier we mentioned findings indicating that emotionally reactive toddlers function worse than other children when exposed to inept parenting, yet benefit most from good parenting. Researchers have become increasingly interested in temperamental differences in children's susceptibility (or responsiveness) to environmental influences (Pluess & Belsky, 2011). Using molecular genetic analyses, they are clarifying how these *gene-environment interactions* operate.

© PHOTOFUSION/UNIVERSAL IMAGES GROUP EDITORIAL/GETTY IMAGES

How will this mother respond to her daughter's anger and distress? With patience and support, emotionally reactive toddlers develop especially favorably. But when exposed to hostile, rejecting parenting, they fare worse than other children, quickly becoming aggressive and defiant.

**FIGURE 6.1** Angry reactivity at age 3 in response to positive and negative maternal behaviors for children with and without the short 5-HTTLPR genotype. Children with a high-risk genotype (with the genetic marker) were highly susceptible to parenting quality—both good and bad. They displayed little anger when exposed to maternal affection and encouragement but high anger to maternal insensitivity and hostility. Children with a low-risk genotype (without the genetic marker) responded little to quality of maternal behavior. (Adapted from P. T. Davies and D. Cicchetti, 2014, “How and Why Does the 5-HTTLPR Gene Moderate Associations Between Maternal Unresponsiveness and Children’s Disruptive Problems?” *Child Development*, 85, p. 494. Adapted by permission of John Wiley & Sons.)

Consistently, young children with a chromosome 7 gene containing a certain repetition of base pairs called short 5-HTTLPR—which interferes with functioning of the inhibitory neurotransmitter serotonin and, thus, greatly increases the risk of self-regulation difficulties—display high susceptibility to effects of parenting quality. Those exposed to maladaptive parenting readily develop externalizing problems. But when parenting is kind and supportive, children with the genetic marker fare exceedingly well in adjustment (Kochanska et al., 2011; van IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012). Among children without the 5-HTTLPR genotype, parenting—whether positive or negative—has minimal impact on externalizing symptoms.

Findings from a two-year follow-up of 1-year-olds from poverty-stricken families provide an impressive illustration (see Figure 6.1) (Davies & Cicchetti, 2014). Toddlers with the high-risk 5-HTTLPR genotype subjected to inept parenting became increasingly reactive emotionally to their mother’s hostile, rejecting behavior, responding with distress, anger, and uncontrolled screaming. Their negative emotionality, in turn, predicted a sharp rise in aggression and defiance by age 3. In contrast, high-risk toddlers of affectionate, encouraging mothers displayed effective emotion regulation and far less anger and aggression than children with a low-risk genotype! Low-risk children barely reacted to variation in parenting quality.

As these outcomes reveal, young children with the short 5-HTTLPR genetic marker show unusually high early *plasticity*

(see page 9 in Chapter 1 to review). Their emotion regulation is particularly susceptible to the effects of both good and poor parenting. Because children with this “susceptibility attribute” fare better than other children when parenting is supportive, they are likely to benefit most from interventions aimed at reducing parental stress and promoting responsive child rearing.

**Siblings’ Unique Experiences.** In families with several children, an additional influence on temperament is at work: When parents are asked to describe each of their children’s personalities, they often look for differences between siblings: “She’s a lot more active,” “He’s more sociable,” “She’s far more persistent.” As a result, parents often regard siblings as more distinct than other observers do.

In a large study of 1- to 3-year-old twin pairs, parents rated identical twins as less alike in temperament than researchers’ ratings indicated. And whereas researchers rated fraternal twins as moderately similar, parents viewed them as somewhat opposite in temperament (Saudino, 2003). This tendency to emphasize each child’s unique qualities affects parenting practices. Each child, in turn, evokes responses from caregivers that are consistent with parental beliefs and the child’s developing temperament.

Besides different experiences within the family, siblings have distinct experiences with teachers, peers, and others in their community that affect personality development. And as we will see in Chapter 9, in middle childhood and adolescence, siblings often seek ways to differ from one another. For all these reasons, both identical and fraternal twins tend to become increasingly dissimilar in personality with age (Loehlin & Martin, 2001). In sum, temperament and personality can be understood only in terms of complex interdependencies between genetic and environmental factors.

## Temperament and Child Rearing: The Goodness-of-Fit Model

Thomas and Chess (1977) proposed a **goodness-of-fit model** to explain how temperament and environment can together produce favorable outcomes. Goodness of fit involves creating child-rearing environments that recognize each child’s temperament while simultaneously encouraging more adaptive functioning. If a child’s disposition interferes with learning or getting along with others, adults must gently but consistently counteract the child’s maladaptive style.

Difficult children (who withdraw from new experiences and react negatively and intensely) frequently experience parenting that fits poorly with their dispositions. As infants, they are less likely to receive sensitive caregiving. By the second year, their parents tend to resort to angry, punitive discipline, which undermines the development of effortful control. As the child reacts with defiance and disobedience, parents become increasingly stressed. As a result, they continue their coercive tactics and also discipline inconsistently, at times rewarding the child’s noncom-

pliance by giving in to it (Lee et al., 2012; Paulussen-Hoogeboom et al., 2007; Pesonen et al., 2008). These practices sustain and even increase the child’s irritable, conflict-ridden style.

In contrast, when parents are positive and sensitive, which helps infants and toddlers—especially those who are emotionally reactive—regulate emotion, difficultness declines by age 2 or 3 (Raikes et al., 2007). In toddlerhood and childhood, parental sensitivity, support, clear expectations, and limits foster effortful control, also reducing the likelihood that difficultness will persist and lead to emotional and social difficulties (Cipriano & Stifter, 2010; Raikes et al., 2007).

Cultural values also affect the fit between parenting and child temperament, as research in China illustrates. In the past, high valuing of social harmony, which discourages self-assertion, led Chinese adults to evaluate shy children positively. But rapid expansion of a market economy, which requires assertiveness and sociability for success, may be responsible for a change in Chinese parents’ and teachers’ attitudes toward childhood shyness (Chen, Wang, & DeSouza, 2006; Yu, 2002). Whereas shyness was positively correlated with teacher-rated competence, peer acceptance, leadership, and academic achievement in 1990, these relationships weakened in 1998 and reversed in 2002, when they mirrored findings of Western research (Chen et al., 2005). But positive valuing of shyness persists in rural areas of China, where shy children continue to enjoy high social status and are well-adjusted (Chen, Wang, & Cao, 2011). Cultural context makes a difference in whether shy children fare well or poorly.

An effective match between rearing conditions and child temperament is best accomplished early, before unfavorable temperament–environment relationships produce maladjustment. The goodness-of-fit model reminds us that children have unique dispositions that adults must accept. Parents can neither take full credit for their children’s virtues nor be blamed for all their faults. But parents can turn an environment that exaggerates a child’s problems into one that builds on the child’s strengths. As we will see next, goodness of fit is also at the heart of infant–caregiver attachment. This first intimate relationship grows out of interaction between parent and baby, to which the emotional styles of both partners contribute.

## Ask yourself

**CONNECT** Explain how findings on ethnic and gender differences in temperament illustrate gene–environment correlation, discussed on pages 68–69 in Chapter 2.

**APPLY** Mandy and Jeff are parents of 2-year-old inhibited Sam and 3-year-old difficult Maria. Explain the importance of effortful control to Mandy and Jeff, and suggest ways they can strengthen it in each of their children.

**REFLECT** How would you describe your temperament as a young child? Do you think your temperament has remained stable, or has it changed? What factors might be involved?

## Development of Attachment

- 6.6** Describe the development of attachment during the first two years.
- 6.7** How do researchers measure attachment security, what factors affect it, and what are its implications for later development?
- 6.8** Describe infants' capacity for multiple attachments.

**Attachment** is the strong affectionate tie we have with special people in our lives that leads us to feel pleasure when we interact with them and to be comforted by their nearness in times of stress. By the second half-year, infants have become attached to familiar people who have responded to their needs. Consider how babies of this age single out their parents for special attention: When the parent enters the room, the baby breaks into a broad, friendly smile. When she picks him up, he pats her face, explores her hair, and snuggles against her. When he feels anxious or afraid, he crawls into her lap and clings closely.

Freud first suggested that the infant's emotional tie to the mother is the foundation for all later relationships. Contemporary research indicates that—although the parent–infant bond is vitally important—later development is influenced not just by early attachment experiences but also by the continuing quality of the parent–child relationship.

NINA LEEN/TIME LIFE PICTURES/GETTY IMAGES

Baby monkeys reared with “surrogate mothers” preferred to cling to a soft terry-cloth “mother” over a wire-mesh “mother” holding a bottle—evidence that parent–infant attachment is based on more than satisfaction of hunger.

Attachment has also been the subject of intense theoretical debate. Recall that the *psychoanalytic perspective* regards feeding as the central context in which caregivers and babies build this close emotional bond. *Behaviorism*, too, emphasizes the importance of feeding, but for different reasons. According to a well-known behaviorist explanation, infants learn to prefer the mother's soft caresses, warm smiles, and tender words because these events are paired with tension relief as she satisfies the baby's hunger.

Although feeding is an important context for building a close relationship, attachment does not depend on hunger satisfaction. In the 1950s, a famous experiment showed that rhesus monkeys reared with terry-cloth and wire-mesh “surrogate mothers” clung to the soft terry-cloth substitute, even though the wire-mesh “mother” held the bottle and infants had to climb onto it to be fed (Harlow & Zimmerman, 1959). Human infants, too, become attached to family members who seldom feed them, including fathers, siblings, and grandparents. And toddlers in Western cultures who sleep alone and experience frequent daytime separations from their parents sometimes develop strong emotional ties to cuddly objects, such as blankets and teddy bears, that play no role in infant feeding!

## Bowlby's Ethological Theory

Today, **ethological theory of attachment**, which recognizes the infant's emotional tie to the caregiver as an evolved response that promotes survival, is the most widely accepted view. John Bowlby (1969), who first applied this perspective to the infant–caregiver bond, retained the psychoanalytic idea that quality of attachment to the caregiver has profound implications for the child's feelings of security and capacity to form trusting relationships.

At the same time, Bowlby was inspired by Konrad Lorenz's studies of imprinting (see Chapter 1). Bowlby believed that the human infant, like the young of other animal species, is endowed with a set of built-in behaviors that help keep the parent nearby to protect the infant from danger and to provide support for exploring and mastering the environment. Contact with the parent also ensures that the baby will be fed, but Bowlby pointed out that feeding is not the basis for attachment. Rather, attachment can best be understood in an evolutionary context in which survival of the species—through ensuring both safety and competence—is of utmost importance.

According to Bowlby, the infant's relationship with the parent begins as a set of innate signals that call the adult to the baby's side. Over time, a true affectionate bond forms, supported by new cognitive and emotional capacities as well as by a history of warm, sensitive care. Attachment develops in four phases:

1. *Preattachment phase (birth to 6 weeks)*. Built-in signals—grasping, smiling, crying, and gazing into the adult's eyes—help bring newborn babies into close contact with other humans, who comfort them. Newborns prefer their own mother's smell, voice, and face (see Chapters 3 and 4). But

they are not yet attached to her, since they do not mind being left with an unfamiliar adult.

2. *“Attachment-in-the-making” phase (6 weeks to 6–8 months).* During this phase, infants respond differently to a familiar caregiver than to a stranger. For example, at 4 months, Timmy smiled, laughed, and babbled more freely when interacting with his mother and quieted more quickly when she picked him up. As infants learn that their own actions affect the behavior of those around them, they begin to develop a *sense of trust*—the expectation that the caregiver will respond when signaled—but they still do not protest when separated from her.
3. *“Clear-cut” attachment phase (6–8 months to 18 months–2 years).* Now attachment to the familiar caregiver is evident. Babies display **separation anxiety**, becoming upset when their trusted caregiver leaves. Like stranger anxiety (see page 186), separation anxiety does not always occur; it depends on infant temperament and the current situation. But in many cultures, separation anxiety increases between 6 and 15 months. Besides protesting the parent’s departure, older infants and toddlers try hard to maintain her presence. They approach, follow, and climb on her in preference to others. And they use the familiar caregiver as a secure base from which to explore.
4. *Formation of a reciprocal relationship (18 months to 2 years and on).* By the end of the second year, rapid growth in representation and language enables toddlers to understand some of the factors that influence the parent’s coming and going and to predict her return. As a result, separation protest declines. Now children negotiate with the caregiver, using requests and persuasion to alter her goals. For example, at age 2, Caitlin asked Carolyn and David to read her a story before leaving her with a babysitter. The extra time with her parents, along with a better understanding of where they were going (“to have dinner with Uncle Sean”) and when they would be back (“right after you go to sleep”), helped Caitlin withstand her parents’ absence.

According to Bowlby (1980), out of their experiences during these four phases, children construct an enduring affectionate tie to the caregiver that they can use as a secure base in the parents’ absence. This image serves as an **internal working model**, or set of expectations about the availability of attachment figures and their likelihood of providing support during times of stress. The internal working model becomes a vital part of personality, serving as a guide for all future close relationships (Bretherton & Munholland, 2008).

Consistent with these ideas, as early as the second year, toddlers seem to form attachment-related expectations about parental comfort and support. In one study, securely attached 12- to 16-month-olds looked longer at a video of an unresponsive caregiver (inconsistent with their expectations) than a video of a responsive caregiver. Insecurely attached agemates, in contrast, either looked longer at the responsive caregiver or did not distinguish between the two (Johnson, Dweck, & Chen, 2007; Johnson

© ELLEN B. SENISI

With her teacher’s enticement to play and an explanation that her mother will be back soon, this 2-year-old is likely to separate without tears. Her language and representational skills enable her to predict her mother’s return, so separation anxiety declines.

et al., 2010). The researchers concluded that the toddlers’ visual responses reflected “surprise” at caregiver behavior at odds with their own internal working model. With age, children continually revise and expand their internal working model as their cognitive, emotional, and social capacities increase and as they interact with parents and form other close bonds with adults, siblings, and friends.

## Measuring the Security of Attachment

Although all family-reared babies become attached to a familiar caregiver by the second year, the quality of this relationship varies. Some infants appear relaxed and secure in the presence of the caregiver; they know they can count on her for protection and support. Others seem anxious and uncertain.

A widely used laboratory procedure for assessing the quality of attachment between 1 and 2 years of age is the **Strange Situation**. In designing it, Mary Ainsworth and her colleagues reasoned that securely attached infants and toddlers should use the parent as a secure base from which to explore in an unfamiliar playroom. In addition, when the parent leaves, an unfamiliar adult should be less comforting than the parent. The Strange Situation takes the baby through eight short episodes in which brief separations from and reunions with the parent occur (see Table 6.2 on page 198).

**TABLE 6.2**  
**Episodes in the Strange Situation**

EPISODE	EVENTS	ATTACHMENT BEHAVIOR OBSERVED
1	Researcher introduces parent and baby to playroom and then leaves.	
2	Parent is seated while baby plays with toys.	Parent as a secure base
3	Stranger enters, is seated, and talks to parent.	Reaction to unfamiliar adult
4	Parent leaves room. Stranger responds to baby and offers comfort if baby is upset.	Separation anxiety
5	Parent returns, greets baby, and offers comfort if necessary. Stranger leaves room.	Reaction to reunion
6	Parent leaves room.	Separation anxiety
7	Stranger enters room and offers comfort.	Ability to be soothed by stranger
8	Parent returns, greets baby, offers comfort if necessary, and tries to reinterest baby in toys.	Reaction to reunion

*Note:* Episode 1 lasts about 30 seconds; each of the remaining episodes lasts about 3 minutes. Separation episodes are cut short if the baby becomes very upset. Reunion episodes are extended if the baby needs more time to calm down and return to play.

*Source:* Ainsworth et al., 1978.

Observing infants' responses to these episodes, researchers identified a secure attachment pattern and three patterns of insecurity; a few babies cannot be classified (Ainsworth et al., 1978; Main & Solomon, 1990; Thompson, 2013). Although separation anxiety varies among the groups, the baby's reunion responses define attachment quality. From the description at the beginning of this chapter, which pattern do you think Grace displayed after adjusting to her adoptive family?

- **Secure attachment.** These infants use the parent as a secure base. When separated, they may or may not cry, but if they do, it is because the parent is absent and they prefer her to the stranger. When the parent returns, they convey clear pleasure—some expressing joy from a distance, others asking to be held until settling down to return to play—and crying is reduced immediately. About 60 percent of North American infants in middle-SES families show this pattern. (In low-SES families, a smaller proportion of babies show the secure pattern, with higher proportions falling into the insecure patterns.)
- **Insecure-avoidant attachment.** These infants seem unresponsive to the parent when she is present. When she leaves, they usually are not distressed, and they react to the stranger in much the same way as to the parent. During reunion, they avoid or are slow to greet the parent, and when picked up,

they often fail to cling. About 15 percent of North American infants in middle-SES families show this pattern.

- **Insecure-resistant attachment.** Before separation, these infants seek closeness to the parent and often fail to explore. When the parent leaves, they are usually distressed, and on her return they combine clinginess with angry, resistive behavior (struggling when held, hitting and pushing). Many continue to cry after being picked up and cannot be comforted easily. About 10 percent of North American infants in middle-SES families show this pattern.
- **Disorganized/disoriented attachment.** This pattern reflects the greatest insecurity. At reunion, these infants show confused, contradictory behaviors—for example, looking away while the parent is holding them or approaching the parent with flat, depressed emotion. Most display a dazed facial expression, and a few cry out unexpectedly after having calmed down or display odd, frozen postures. About 15 percent of North American infants in middle-SES families show this pattern.

An alternative method, the **Attachment Q-Sort**, suitable for children between 1 and 5 years, depends on home observation (Waters et al., 1995). Either the parent or a highly trained observer sorts 90 behaviors—such as “Child greets mother with a big smile when she enters the room,” “If mother moves very far, child follows along,” and “Child uses mother’s facial expressions as a good source of information when something looks risky or threatening”—into nine categories ranging from “highly descriptive” to “not at all descriptive” of the child. Then a score, ranging from high to low in security, is computed.

Because the Q-Sort taps a wider array of attachment-related behaviors than the Strange Situation, it may better reflect the parent–infant relationship in everyday life. However, the Q-Sort method is time-consuming, requiring a nonparent informant to spend several hours observing the child before sorting the descriptors, and it does not differentiate between types of insecurity. The Q-Sort responses of expert observers correspond well with babies' secure-base behavior in the Strange Situation, but parents' Q-Sorts do not (van IJzendoorn et al., 2004). Parents of insecure children, especially, may have difficulty accurately reporting their child's attachment behaviors.

## Stability of Attachment

Research on the stability of attachment patterns between 1 and 2 years of age yields a wide range of findings (Thompson, 2006, 2013). A close look at which babies stay the same and which ones change yields a more consistent picture. Quality of attachment is usually secure and stable for middle-SES babies experiencing favorable life conditions. And infants who move from insecurity to security typically have well-adjusted mothers with positive family and friendship ties. Perhaps many became parents before they were psychologically ready but, with social support, grew into the role.

In contrast, in low-SES families with many daily stresses and little social support, attachment generally moves away from

security or changes from one insecure pattern to another (Fish, 2004; Levendosky et al., 2011). And in long-term follow-ups extending from infancy to late adolescence and early adulthood, shifts from security to insecurity were associated with single parenthood, child maltreatment, maternal depression, and poor family functioning and parenting quality (Booth-LaForce et al., 2014; Weinfield, Sroufe, & Egeland, 2000; Weinfield, Whaley, & Egeland, 2004).

These findings indicate that securely attached babies more often maintain their attachment status than insecure babies. The exception is disorganized/disoriented attachment, an insecure pattern that either shows greater stability than the other patterns or consistently predicts insecurity of another type in adolescence and early adulthood (Groh et al., 2014; Hesse & Main, 2000; Weinfield, Whaley, & Egeland, 2004). Furthermore, adults with histories of attachment disorganization are at increased risk of having children who display disorganized/disoriented attachment (Raby et al., 2015). As you will soon see, many disorganized/disoriented infants and children experience extremely negative caregiving, which may disrupt emotional self-regulation so severely that confused, ambivalent feelings often persist, impairing child rearing of the next generation.

## Cultural Variations

Cross-cultural evidence indicates that attachment patterns may have to be interpreted differently in certain cultures. For example, as Figure 6.2 reveals, German infants show considerably more avoidant attachment than American babies do. But German par-

**FIGURE 6.2 A cross-cultural comparison of infants' reactions in the Strange Situation.** A high percentage of German babies seem avoidantly attached, whereas a substantial number of Japanese infants appear resistantly attached. Note that these responses may not reflect true insecurity. Instead, they are probably due to cultural differences in child-rearing practices. (Based on van IJzendoorn & Kroonenberg, 1988; van IJzendoorn & Sagi-Schwartz, 2008.)

ents value independence and encourage their infants to be non-clingy (Grossmann et al., 1985). In contrast, a study of infants of the Dogon people of Mali, Africa, revealed that none showed avoidant attachment to their mothers (True, Pisani, & Oumar, 2001). Even when grandmothers are primary caregivers (as they are with firstborn sons), Dogon mothers remain available to their babies, holding them close and nursing them promptly in response to hunger and distress.

Japanese infants, as well, rarely show avoidant attachment (refer again to Figure 6.2). Rather, many are resistantly attached, but this reaction may not represent true insecurity. Japanese mothers rarely leave their babies in others' care, so the Strange Situation probably induces greater stress in them than in babies who frequently experience maternal separations (Takahashi, 1990). Also, Japanese parents view the attention seeking that is part of resistant attachment as a normal indicator of infants' efforts to satisfy dependency and security needs (Rothbaum, Morelli, & Rusk, 2011). Despite these and other cultural variations, the secure pattern is still the most common attachment quality in all societies studied (van IJzendoorn & Sagi-Schwartz, 2008).

## Factors That Affect Attachment Security

What factors might influence attachment security? Researchers have looked closely at four important influences: (1) early availability of a consistent caregiver, (2) quality of caregiving, (3) the baby's characteristics, and (4) family context, including parents' internal working models.

**Early Availability of a Consistent Caregiver.** What happens when a baby does not have the opportunity to establish a close tie to a caregiver? To find out, researchers followed the development of infants in an institution with a good caregiver-child ratio and a rich selection of books and toys. However, staff turnover was so rapid that the average child had 50 caregivers by age 4½. Many of these children became "late adoptees" who were placed in homes after age 4. Most developed deep ties with their adoptive parents, indicating that a first attachment can develop as late as 4 to 6 years of age (Hodges & Tizard, 1989; Tizard & Rees, 1975). But these children were more likely to display attachment difficulties, including an excessive desire for adult attention, "overfriendliness" to unfamiliar adults and peers, failure to check back with the parent in anxiety-arousing situations, and few friendships.

Children who spent their first year or more in deprived Eastern European orphanages—though also able to bond with their adoptive parents—show greatly elevated rates of attachment insecurity (Lionetti, Pastore, & Barone, 2015; Smyke et al., 2010; van den Dries et al., 2009). And they, too, are at high risk for emotional and social difficulties. Whereas many are indiscriminately friendly, others are sad, anxious, and withdrawn (Bakermans-Kranenburg et al., 2011; O'Connor et al., 2003). These symptoms typically persist and are associated with

wide-ranging mental health problems in middle childhood and adolescence, including cognitive impairments, inattention and overactivity, depression, and either social avoidance or aggressive behavior (Kreppner et al., 2010; Rutter et al., 2007, 2010).

Furthermore, as early as 7 months, institutionalized children show reduced ERP brain waves in response to facial expressions of emotion and have trouble discriminating such expressions—outcomes that suggest disrupted formation of neural structures involved in “reading” emotions (Parker et al., 2005). Consistent with these findings, in adopted children with longer institutional stays, the volume of the *amygdala* (see page 192) is atypically large (Tottenham et al., 2011). The larger the amygdala, the worse adopted children perform on tasks assessing understanding of emotion and the poorer their emotional self-regulation. Overall, the evidence indicates that fully normal emotional development depends on establishing a close tie with a caregiver early in life.

**Quality of Caregiving.** Dozens of studies report that **sensitive caregiving**—responding promptly, consistently, and appropriately to infants and holding them tenderly and carefully—is moderately related to attachment security in diverse cultures and SES groups (Belsky & Fearon, 2008; van IJzendoorn et al., 2004). Mothers of securely attached babies also frequently refer to their infants’ mental states and motives: “You really *like* that swing.” “Do you *remember* Grandma?” This *maternal mind-mindedness*—tendency to treat the baby as a person with inner thoughts and feelings—seems to promote sensitive caregiving (Meins, 2013; Meins et al., 2012). In contrast, insecurely attached infants tend to have mothers who engage in less physical contact, handle them awkwardly or “routinely,” and are sometimes

resentful and rejecting, particularly in response to infant distress (Ainsworth et al., 1978; McElwain & Booth-LaForce, 2006; Pederson & Moran, 1996).

Also, in studies of Western babies, a special form of communication called **interactional synchrony** separates the experiences of secure from insecure babies. It is best described as a sensitively tuned “emotional dance,” in which the caregiver responds to infant signals in a well-timed, rhythmic, appropriate fashion. In addition, both partners match emotional states, especially the positive ones (Bigelow et al., 2010; Isabella & Belsky, 1991). Earlier we saw that sensitive face-to-face play, in which interactional synchrony occurs, increases babies’ responsiveness to others’ emotional messages and also helps infants regulate emotion.

Cultures, however, vary greatly in their view of sensitivity toward infants. In Western societies that highly value independence, sensitive caregiving follows the baby’s lead by being contingently responsive to infant signals, “reading” the baby’s mental states, and supporting exploration. In non-Western village communities and Asian cultures, caregiving that keeps the baby physically close, dampens emotional expressiveness, and teaches social appropriateness is deemed sensitive because it advances the child’s connectedness to others and promotes social harmony (Morelli, 2015; Otto & Keller, 2014). Among the Gusii people of Kenya, for example, mothers are quick to quiet their infants and satisfy their physical needs, but they rarely interact playfully with them. Yet most Gusii infants are securely attached (LeVine et al., 1994). This suggests that security depends on attentive caregiving, not necessarily on contingent interaction. Puerto Rican mothers, who highly value obedience and socially appropriate behavior, often physically direct and limit their babies’

**Left:** A father and baby engage in interactional synchrony, matching expressions of positive emotion in face-to-face play—a form of parental sensitivity that predicts attachment security in Western cultures. **Right:** In non-Western village communities and Asian cultures, parental sensitivity directed at physical closeness, calmness, and promptly meeting physical needs is linked to attachment security.

actions—a caregiving style linked to attachment security in Puerto Rican culture (Carlson & Harwood, 2003). Yet in Western cultures, such physical control and restriction of exploration predict insecurity (Whipple, Bernier, & Mageau, 2011).

Compared with securely attached infants, avoidant babies tend to receive overstimulating, intrusive care. Their mothers might, for example, talk energetically to them while they are looking away or falling asleep. By avoiding the mother, these infants appear to be escaping from overwhelming interaction. Resistant infants often experience inconsistent care. Their mothers are unresponsive to infant signals, yet when the baby begins to explore, they interfere, shifting the infant's attention back to themselves. As a result, the baby is overly dependent as well as angry at the mother's lack of involvement (Cassidy & Berlin, 1994).

Highly inadequate caregiving is a powerful predictor of disruptions in attachment. Child abuse and neglect (topics we will consider in Chapter 8) are associated with all three forms of attachment insecurity. Among maltreated infants, disorganized/disoriented attachment is especially common (Cyr et al., 2010). Persistently depressed mothers, mothers with very low marital satisfaction, and parents suffering from a traumatic event, such as serious illness or loss of a loved one, also tend to promote the uncertain behaviors of this pattern (Campbell et al., 2004; Madigan et al., 2006). And some mothers of disorganized/disoriented infants engage in frightening, contradictory, and unpleasant behaviors, such as looking scared, teasing the baby, holding the baby stiffly at a distance, roughly pulling the baby by the arm, or seeking reassurance from the upset child (Hesse & Main, 2006; Solomon & George, 2011).

**Infant Characteristics.** Because attachment is the result of a *relationship* between two partners, infant characteristics should affect how easily it is established. In Chapter 3 we saw that prematurity, birth complications, and newborn illness make caregiving more taxing. In families under stress, these difficulties are linked to attachment insecurity (Candelaria, Teti, & Black, 2011). But at-risk newborns whose parents have adequate time and patience to care for them fare quite well in attachment security (Brisch et al., 2005).

With respect to temperament, babies who are emotionally reactive are more likely to develop later insecure attachments (van IJzendoorn et al., 2004; Vaughn, Bost, & van IJzendoorn, 2008). And disorganized newborn behavior, evident in NBAS scores (see Chapter 3), increases the risk of disorganized/disoriented attachment (Spangler, Fremmer-Bomik, & Grossmann, 1996).

Again, however, evidence highlighting gene–environment interactions suggests that parental mental health and caregiving are involved. Babies with the short 5-HTTLPR genetic marker, which is associated with emotional reactivity, are more likely than infants with a low-risk genotype to exhibit disorganized/disoriented attachment, but only when caregiving is insensitive (Spangler et al., 2009). In other research, mothers' experience of

trauma was associated with attachment disorganization, but only in infants with a chromosome-11 gene having a certain repetition of DNA base pairs, called DRD4 7-repeat, which is linked to impulsive, overactive behavior (van IJzendoorn & Bakermans-Kranenburg, 2006). These babies, who face self-regulation challenges, were more susceptible to the negative impact of maternal adjustment problems.

If children's temperaments alone determined attachment security, we would expect attachment, like temperament, to be at least moderately heritable. Yet the heritability of attachment is virtually nil (Roisman & Fraley, 2008). Rather, babies with certain genotypes are at increased risk for attachment insecurity when they also experience insensitive parenting. In fact, about two-thirds of siblings establish similar attachment patterns with their parent, although siblings often differ in temperament (Cole, 2006). This suggests that most parents try to adjust their caregiving to each child's individual needs.

Interventions that teach parents to interact sensitively with difficult-to-care-for babies enhance both sensitive caregiving and attachment security (van IJzendoorn & Bakermans-Kranenburg, 2015). One program that focused on both maternal sensitivity and effective discipline was particularly successful in reducing irritable distress and disruptive behavior in toddlers with the DRD4 7-repeat (Bakermans-Kranenburg & van IJzendoorn, 2008a, 2008b). These findings suggest that the DRD4 7-repeat—like the short 5-HTTLPR genetic marker—makes children more susceptible to the effects of both negative and positive parenting.

**Family Circumstances.** Shortly after Timmy's birth, his parents divorced and his father moved to a distant city. Anxious and distracted, Vanessa placed 2-month-old Timmy in Ginette's child-care home and began working 50-hour weeks to make ends meet. On days Vanessa stayed late at the office, a babysitter picked Timmy up, gave him dinner, and put him to bed. Once or twice a week, Vanessa retrieved Timmy from child care. As he neared his first birthday, Vanessa noticed that unlike the other children, who reached out, crawled, or ran to their parents, Timmy ignored her.

Timmy's behavior reflects a repeated finding: Job loss, a failing marriage, financial difficulties, or parental psychological problems (such as anxiety or depression) can undermine attachment indirectly by interfering with parental sensitivity. These stressors can also affect babies' sense of security directly, by altering the emotional climate of the family (for example, exposing them to angry adult interactions) or by disrupting familiar daily routines (Thompson, 2013). (See the Social Issues: Health box on pages 202–203 to find out how child care affects attachment and child adjustment.) By reducing parental stress and improving parent–child communication, social support fosters attachment security (Moss et al., 2005). Ginette's sensitivity toward Timmy was helpful, as was the parenting advice Vanessa received from Ben, a psychologist. As Timmy turned 2, his relationship with his mother seemed warmer.

## Social Issues: Health

### Does Child Care in Infancy Threaten Attachment Security and Later Adjustment?

**A**re infants who experience daily separations from their employed parents and early placement in child care at risk for attachment insecurity and development problems? Some researchers think so, but others disagree (Belsky, 2005; O'Brien et al., 2014).

The best current evidence comes from the National Institute of Child Health and Development (NICHD) Study of Early Child Care, the largest longitudinal investigation of the effects of child care to date, which included more than 1,300 infants and their families. It confirmed that use of nonparental care by itself does not affect attachment quality (NICHD Early Child Care Research Network, 2001). Rather, the relationship between child care and emotional well-being depends on both family and child-care experiences.

#### Family Circumstances

We have seen that family conditions affect children's attachment security and later adjustment. The NICHD Study showed that parenting quality, based on a combination of maternal sensitivity and HOME scores (see page 170 in Chapter 5), exerted a more powerful impact on children's adjustment than

did exposure to child care (NICHD Early Childhood Research Network, 1998; Watamura et al., 2011).

For employed parents, balancing work and caregiving can be stressful. Mothers who are fatigued and anxious because they feel overloaded by work and family pressures may respond less sensitively to their babies, thereby risking the infant's security. As paternal involvement in caregiving has risen (see page 204), many more U.S. fathers in dual-earner families also report role overload (Galinsky, Aumann, & Bond, 2009).

#### Quality and Extent of Child Care

Nevertheless, poor-quality child care may contribute to a higher rate of insecure attachment. In the NICHD Study, when babies were exposed to combined home and child-care risk factors—insensitive caregiving at home along with insensitive caregiving in child care, long hours in child care, or more than one child-care arrangement—the rate of attachment insecurity increased. Overall, mother-child interaction was more favorable when children attended higher-quality child care and also spent fewer hours in child care (NICHD Early Child Care Research Network, 1997, 1999).

Furthermore, when these children reached age 3, a history of higher-quality child care predicted better social skills (NICHD Early Child Care Research Network, 2002b). However, at age 4½ to 5, children averaging more than 30 child-care hours per week displayed externalizing problems, especially defiance, disobedience, and aggression. For those who had been in child-care centers as opposed to family child-care homes, this outcome persisted through elementary school (Belsky et al., 2007b; NICHD Early Child Care Research Network, 2003a, 2006).

But these findings do not necessarily mean that child care causes behavior problems. Rather, heavy exposure to substandard care, which is widespread in the United States, may promote these difficulties, especially when combined with family risk factors. A closer look at the NICHD participants during the preschool years revealed that those in both poor-quality home and child-care environments fared worst in problem behaviors, whereas those in both high-quality home and child-care environments fared best. In between were preschoolers in high-quality child care but poor-quality homes (Watamura et al., 2011). These children benefited from the *protective influence* of high-quality child care.

Evidence from other industrialized nations confirms that full-time child care need not

**Parents' Internal Working Models.** Parents bring to the family context their own history of attachment experiences, from which they construct internal working models that they apply to the bonds they establish with their children. Monica, who recalled her mother as tense and preoccupied, expressed regret that they had not had a closer relationship. Is her image of parenthood likely to affect Grace's attachment security?

To assess parents' internal working models, researchers ask them to evaluate childhood memories of attachment experiences (Main & Goldwyn, 1998). Parents who discuss their childhoods with objectivity and balance, regardless of whether their experiences were positive or negative, tend to behave sensitively and have securely attached children. In contrast, parents who dismiss the importance of early relationships or describe them in angry, confused ways usually have insecurely attached children and are less warm, sensitive, and encouraging of learning and mastery (Behrens, Hesse, & Main, 2007; McFarland-Piazza et al., 2012; Shafer et al., 2015).

But we must not assume any direct transfer of parents' childhood experiences to quality of attachment with their own children. Internal working models are *reconstructed memories* affected by many factors, including relationship experiences over the life course, personality, and current life satisfaction. Longitudinal research reveals that negative life events can weaken the link between an individual's own attachment security in infancy and a secure internal working model in adulthood. And insecurely attached babies who become adults with insecure internal working models often have lives that, based on self-reports in adulthood, are filled with family crises (Waters et al., 2000; Weinfield, Sroufe, & Egeland, 2000).

In sum, our early rearing experiences do not destine us to become either sensitive or insensitive parents (Bretherton & Munholland, 2008). Rather, the way we *view* our childhoods—our ability to come to terms with negative events, to integrate new information into our working models, and to look back on our own parents in an understanding, forgiving way—is far more

harm children's development. For example, amount of time spent in child care in Australia and Norway, which offer high-quality, government-subsidized center-based care, is unrelated to children's behavior problems (Love et al., 2003; Zachrisson et al., 2013).

Still, some children may be particularly stressed by long child-care hours. In one study, children who were rated as highly fearful by their caregivers and who attended child-care centers for full days showed a sharp increase in cortisol levels across the child-care day—a pattern that did not occur on days they spent at home (Watamura et al., 2003). Inhibited children may find the constant company of large numbers of peers particularly stressful. A secure attachment to a professional caregiver, however, is protective (Badanes, Dmitrieva, & Watamura, 2012). It is associated with falling cortisol levels across the child-care day.

### Conclusions

Taken together, research suggests that some infants may be at risk for attachment insecurity and adjustment problems due to inadequate child care, long hours in such care, and parental role overload. But it is inappropriate to use these findings to justify a reduction in child-care services. When family incomes are limited or mothers who want to work

are forced to stay at home, children's emotional security is not promoted.

Instead, it makes sense to increase the availability of high-quality child care and to provide parents with paid employment leave (see page 103 in Chapter 3) and opportunities for part-time work. In the NICHD Study, part-time (as opposed to full-time) employment during the baby's first year was associated with greater maternal sensitivity and a higher-quality home environment, which yielded more favorable development in early childhood (Brooks-Gunn, Han, & Waldfogel, 2010).

Finally, the professional caregiver's relationship with the baby is vital. When caregiver-child ratios are generous, group sizes are small, and caregivers are educated about child development and child rearing, caregivers' interactions are more positive, their attach-

ments to babies are more secure, and children develop more favorably—cognitively, emotionally, and socially (Biringen et al., 2012; NICHD Early Child Care Research Network, 2000b, 2002a, 2006). Child care with these characteristics can become part of an ecological system that relieves parental and child stress, thereby promoting healthy attachment and development.

© ELLEN B. SENISI

High-quality child care, with generous caregiver-child ratios, small group sizes, and knowledgeable caregivers, can be part of a system that promotes all aspects of development, including attachment security.

influential in how we rear our children than the actual history of care we received.

## Multiple Attachments

Babies develop attachments to a variety of familiar people—not just mothers but also fathers, grandparents, siblings, and professional caregivers. Although Bowlby (1969) believed that infants are predisposed to direct their attachment behaviors to a single special person, especially when they are distressed, his theory allows for these multiple attachments.

**Fathers.** When anxious or unhappy, most babies prefer to be comforted by their mother. But this preference typically declines over the second year. And when babies are not distressed, they approach, vocalize to, and smile equally often at both parents, who respond similarly to these overtures (Bornstein, 2015; Parke, 2002).

Fathers' sensitive caregiving predicts attachment security, though somewhat less strongly than mothers' (Brown, Mangelsdorf, & Neff, 2012; Lucassen et al., 2011). As infancy progresses, mothers and fathers in many cultures, including Australia, Canada, Germany, India, Israel, Italy, Japan, and the United States, tend to interact differently with their babies. Mothers devote more time to physical care and expressing affection, fathers to playful interaction (Freeman & Newland, 2010; Pleck, 2012).

Also, mothers and fathers tend to play differently. Mothers more often provide toys, talk to infants, and gently play conventional games like pat-a-cake and peekaboo. In contrast, fathers—especially with their infant sons—tend to engage in highly stimulating physical play with bursts of excitement that increase as play progresses (Feldman, 2003). As long as fathers are also sensitive, this stimulating, startling play style helps babies regulate emotion in intensely arousing situations and may prepare them to venture confidently into active, unpredictable contexts,

including novel physical environments and play with peers (Cabrera et al., 2007; Hazen et al., 2010). In a German study, fathers' sensitive, challenging play with preschoolers predicted favorable emotional and social adjustment from kindergarten to early adulthood (Grossmann et al., 2008).

Play is a vital context in which fathers build secure attachments (Newland, Coyl, & Freeman, 2008). It may be especially influential in cultures where long work hours prevent most fathers from sharing in infant caregiving, such as Japan (Shwalb et al., 2004). In many Western nations, however, a strict division of parental roles—mother as caregiver, father as playmate—has changed over the past several decades in response to women's workforce participation and to cultural valuing of gender equality.

### LOOK and LISTEN

Observe parents at play with infants at home or a family gathering, describing both similarities and differences in mothers' and fathers' behaviors. Are your observations consistent with research findings?

National surveys of thousands of U.S. married couples with children reveal that fathers' family roles have changed substantially over time. As Figure 6.3 reveals, though their involvement continues to fall far short of mothers', today's fathers spend nearly three times as much time caring for children as fathers did in 1965—largely due to the dramatic rise in maternal employment (Pew Research Center, 2015e). Paternal availability to children is fairly similar across U.S. SES and ethnic groups, with one exception: Hispanic fathers spend more time engaged with their infants and young children, probably because of the particularly high value that Hispanic cultures place on family involvement (Cabrera, Aldoney, & Tamis-LeMonda, 2014; Hofferth, 2003).

**FIGURE 6.3** Average hours per week U.S. mothers and fathers reported devoting to caring for children in 1965 and 2011. In national surveys of thousands of married couples, mothers' time spent caring for children between birth and age 18 years increased moderately from 1965 to 2011. Though falling far short of mothers', fathers' time devoted to children rose nearly threefold. (Based on Pew Research Center, 2015e.)

A warm marital bond and supportive coparenting promote both parents' sensitivity and involvement and children's attachment security, but they are especially important for fathers (Brown et al., 2010; Laurent, Kim, & Capaldi, 2008). See the Cultural Influences box on the following page for cross-cultural evidence documenting this conclusion—and also highlighting the powerful role of paternal involvement in children's development.

**Siblings.** Despite declines in family size, nearly 80 percent of U.S. children grow up with at least one sibling (U.S. Census Bureau, 2015d). The arrival of a new baby is a difficult experience for most preschoolers, who often become demanding, clingy, and less affectionate with their parents for a time. Attachment security also typically declines, especially for children over age 2 (old enough to feel threatened and displaced) and for those with mothers under stress (Teti et al., 1996; Volling, 2012).

Yet resentment is only one feature of a rich emotional relationship that soon develops between siblings. Older children also show affection and concern—kissing and patting the baby and calling out, “Mom, he needs you,” when the infant cries. By the end of the first year, babies usually spend much time with older siblings and are comforted by the presence of a preschool-age brother or sister during short parental absences. Throughout childhood, children continue to treat older siblings as attachment figures, turning to them for comfort in stressful situations when parents are unavailable (Seibert & Kerns, 2009).

Nevertheless, individual differences in sibling relationships emerge soon after the new baby's arrival. Certain temperamental traits—high emotional reactivity or activity level—increase the chances of sibling conflict (Brody, Stoneman, & McCoy, 1994; Dunn, 1994). And maternal warmth toward both children is related to positive sibling interaction and to preschoolers' support of a distressed younger sibling (Volling, 2001; Volling &

© ELLEN B. SENIŠI

The arrival of a baby brother or sister is a difficult experience for most preschoolers. Maternal warmth toward both children assures the older sibling of continuing parental love, models affectionate caring, and is related to positive sibling interaction.

## Cultural Influences

### The Role of Fathers' Involvement in Children's Development

In studies of many societies and ethnic groups around the world, researchers coded fathers' expressions of love and nurturance—evident in such behaviors as cuddling, hugging, comforting, playing, verbally expressing love, and praising the child's behavior. Fathers' sustained affectionate involvement predicted later cognitive, emotional, and social competence as strongly as did mothers'—and occasionally more strongly (Rohner & Veneziano, 2001; Veneziano, 2003). In Western cultures, paternal warmth and secure attachment are associated with higher academic achievement, better social skills, and a reduction in child and adolescent behavior problems (Bornstein, 2015; Lamb & Lewis, 2013; Michiels et al., 2010).

What factors promote fathers' involvement? Cross-cultural research reveals a consistent association between the amount of time fathers spend near infants and toddlers and their expressions of caring and affection (Rohner & Veneziano, 2001). Consider the Aka hunters and gatherers of Central Africa, where fathers spend more time in physical proximity to their babies than in any other

known society. Aka fathers are within arm's reach of infants more than half the day, and they pick up, cuddle, and play with their babies at least five times as often as fathers in other hunting-and-gathering societies. Why are Aka fathers so involved? The bond between Aka husband and wife is unusually cooperative and intimate. Throughout the day, couples share hunting, food preparation, and social and leisure activities (Hewlett, 1992). The more time Aka parents are together, the greater the father's loving interaction with his baby.

In Western cultures as well, happily married fathers whose partners coparent cooperatively with them spend more time with and interact more effectively with infants. In contrast, marital dissatisfaction is associated with

insensitive paternal care (Brown et al., 2010; Seigny & Loutzenhiser, 2010). Clearly, fathers' relationships with their partners and their babies are closely linked. Evidence for the power of fathers' involvement, reported in virtually every culture and ethnic group studied, is reason to encourage and support their nurturing care of young children.

© DANIEL DEMPSTER PHOTOGRAPHY/ALAMY

In both Western and non-Western nations, fathers' sustained, affectionate involvement predicts long-term favorable cognitive, emotional, and social development.

Belsky, 1992). In contrast, maternal harshness and lack of involvement are linked to antagonistic sibling relationships (Howe, Aquan-Assee, & Bukowski, 2001).

Finally, a good marriage is correlated with older preschool siblings' capacity to cope adaptively with jealousy and conflict (Volling, McElwain, & Miller, 2002). Perhaps good communication between parents serves as a model of effective problem solving. It may also foster a generally happy family environment, giving children less reason to feel jealous.

Refer to Applying What We Know on page 206 for ways to promote positive relationships between babies and their preschool siblings. Siblings offer a rich social context in which young children learn and practice a wide range of skills, including affectionate caring, conflict resolution, and control of hostile and envious feelings.

### Attachment and Later Development

According to psychoanalytic and ethological theories, the inner feelings of affection and security that result from a healthy

attachment relationship support all aspects of psychological development. Consistent with this view, an extended longitudinal study found that preschoolers who had been securely attached as babies were rated by their teachers as higher in self-esteem, empathy, and social skills than were their insecurely attached counterparts, who displayed more behavior problems. When studied again at age 11, children who had been secure infants continued to be more socially competent. And as these well-functioning school-age children became adolescents and young adults, they continued to benefit from more supportive social networks, formed more stable and gratifying romantic relationships, and attained higher levels of education (Elicker, Englund, & Sroufe, 1992; Sroufe, 2002; Sroufe et al., 2005).

For some researchers, these findings indicate that secure attachment in infancy causes improved cognitive, emotional, and social competence in later years. Yet contrary evidence exists. In other longitudinal studies, secure infants generally fared better than insecure infants, but not always (Fearon et al., 2010; McCartney et al., 2004; Schneider, Atkinson, & Tardif, 2001; Stams, Juffer, & van IJzendoorn, 2002).

## Applying what we Know

### Encouraging Affectionate Ties Between Infants and Their Preschool Siblings

SUGGESTION	DESCRIPTION
Spend extra time with the older child.	Parents can minimize the older child's feelings of being deprived of affection and attention by setting aside time to spend with her. Fathers can be especially helpful, planning outings with the preschooler and taking over care of the baby so the mother can be with the older child.
Handle sibling misbehavior with patience.	When parents respond patiently to the older sibling's misbehavior and demands for attention, these reactions are usually temporary. Parents can give the preschooler opportunities to feel proud of being more grown-up than the baby—for example, by encouraging the older child to assist with feeding, bathing, dressing, and offering toys, and showing appreciation for these efforts.
Discuss the baby's wants and needs.	By helping the older sibling understand the baby's point of view, parents can promote friendly, considerate behavior. They can say, for example, "He's so little that he just can't wait to be fed," or "He's trying to reach his rattle, and he can't."
Express positive emotion toward your partner and engage in effective coparenting.	When parents mutually support each other's parenting behavior, their good communication helps the older sibling cope adaptively with jealousy and conflict.

What accounts for this inconsistency? Mounting evidence indicates that *continuity of caregiving* determines whether attachment security is linked to later development (Lamb et al., 1985; Thompson, 2013). Children whose parents respond sensitively not just in infancy but also in later years generally develop favorably. In contrast, children whose parents behave insensitively or who, over a long period, are exposed to a negative family climate tend to establish lasting patterns of attachment insecurity and are at greater risk for developmental difficulties.

A close look at the relationship between parenting and children's adjustment supports this interpretation. Disorganized/disoriented attachment, a pattern associated with serious parental psychological problems and highly maladaptive caregiving, is strongly linked to internalizing and externalizing difficulties in childhood (Moss et al., 2006; Steele & Steele, 2014). And when researchers tracked a large sample of children from age 1 to 3 years, those with histories of secure attachment followed by sensitive parenting scored highest in cognitive, emotional, and social outcomes. Those with histories of insecure attachment followed by insensitive parenting scored lowest, while those with mixed histories of attachment and maternal sensitivity scored in between (Belsky & Fearon, 2002).

Although a secure attachment in infancy does not guarantee continued good parenting, it does launch the parent–child relationship on a positive path. An early warm, positive parent–child tie, sustained over time, promotes many aspects of children's development: a more confident and complex self-concept, more advanced emotional understanding, greater effortful control, more effective social skills, a stronger sense of moral responsibility, and higher motivation to achieve in school (Drake, Belsky, & Fearon, 2014; Groh et al., 2014; Viddal et al., 2015). But the effects of early attachment security are *conditional*—dependent on the quality of the baby's future relationships. Finally, as we will see again in future chapters, attachment is just one of the complex influences on children's psychological development.

## Ask yourself

**CONNECT** Review research on emotional self-regulation on page 189. How do the caregiving experiences of securely attached infants promote emotional self-regulation?

**APPLY** What attachment pattern did Timmy display when Vanessa arrived home from work, and what factors probably contributed to it?

**REFLECT** How would you characterize your internal working model? What factors, in addition to your relationship with your parents, might have influenced it?

## Self-Development

**6.9** Describe the development of self-awareness in infancy and toddlerhood, along with the emotional and social capacities it supports.

Infancy is a rich formative period for the development of both physical and social understanding. In Chapter 5, you learned that infants develop an appreciation of the permanence of objects. And in this chapter, we have seen that over the first year, infants recognize and respond appropriately to others' emotions and distinguish familiar from unfamiliar people. That both objects and people achieve an independent, stable existence for infants implies that knowledge of the self as a separate, permanent entity is also emerging.

### Self-Awareness

After Caitlin's bath, Carolyn often held her in front of a mirror. As early as the first few months, Caitlin smiled and returned friendly behaviors to her image. At what age did she realize that the baby smiling back was herself?

**Beginnings of Self-Awareness.** At birth, infants sense that they are physically distinct from their surroundings. For example, newborns display a stronger rooting reflex in response to external stimulation (an adult's finger touching their cheek) than to self-stimulation (their own hand contacting their cheek) (Rochat & Hespos, 1997). Newborns' remarkable capacity for *intermodal perception* (see page 143 in Chapter 4) supports the beginnings of self-awareness (Rochat, 2013). As they feel their own touch, feel and watch their limbs move, and feel and hear themselves cry, babies experience intermodal matches that differentiate their own body from surrounding bodies and objects.

Over the first few months, infants distinguish their own visual image from other stimuli, but their self-awareness is limited—expressed only in perception and action. When shown two side-by-side video images of their kicking legs, one from their own perspective (camera behind the baby) and one from an observer's perspective (camera in front of the baby), 3-month-olds looked longer at the observer's view (Rochat, 1998). By 4 months, infants look and smile more at video images of others than at video images of themselves, indicating that they treat another person (as opposed to the self) as a social partner (Rochat & Striano, 2002).

This discrimination of one's own limb and facial movements from those of others in real-time video reflects an *implicit* awareness that the self is distinct from the surrounding world. Implicit self-awareness is also evident in young infants' social expectations—for example, in protest or withdrawal when face-to-face interaction with a responsive adult is disrupted (see page 185). These early signs of self-experience serve as the foundation for development of *explicit* self-awareness—understanding that the self is a unique object in a world of objects.

**Explicit Self-Awareness.** During the second year, toddlers become consciously aware of the self's physical features. In several studies, 9- to 28-month-olds were placed in front of a mirror. Then, under the pretext of wiping the baby's face, each mother rubbed red dye on her child's nose or forehead. Younger babies typically touched the mirror as if the red mark had nothing to do with them. But the majority of those older than 18 to 20 months touched or rubbed their noses or foreheads, indicating awareness of their unique appearance (Bard et al., 2006; Lewis & Brooks-Gunn, 1979).

Around age 2, **self-recognition**—identification of the self as a physically unique being—is well under way. Children point to themselves in photos and refer to themselves by name or with a personal pronoun (“I” or “me”) (Lewis & Ramsay, 2004). Soon children identify themselves in images with less detail and fidelity than mirrors. Around age 2½, most reach for a sticker surreptitiously placed on top of their heads when shown themselves in a live video, and around age 3 most recognize their own shadow (Cameron & Gallup, 1988; Suddendorf, Simcock, & Nielsen, 2007).

Nevertheless, toddlers make **scale errors**, attempting to do things that their body size makes impossible. For example, they will try to put on dolls' clothes, sit in a doll-sized chair, or walk through a doorway too narrow for them to pass through

© ELLEN B. SENISI

This 20-month-old makes silly faces in a mirror, a playful response to her reflection that indicates she is aware of herself as a separate being and recognizes her unique physical features.

(Brownell, Zerwas, & Ramani, 2007; DeLoache et al., 2013). Possibly, toddlers lack an accurate understanding of their own body dimensions. Alternatively, they may simply be exploring the consequences of squeezing into restricted spaces, as they are far less likely to try when the risk of harming themselves is high—for example, if the too-narrow doorway is next to a ledge where they could fall (Franchak & Adolph, 2012). Scale errors decline between ages 2 and 3½.

What experiences contribute to gains in self-awareness? During the first year, as infants act on the environment, they probably notice effects that help them sort out self, other people, and objects (Nadel, Prepin, & Okanda, 2005; Rochat, 2013). For example, batting a mobile and seeing it swing in a pattern different from the infant's own actions informs the baby about the relation between self and physical world. Smiling and vocalizing at a caregiver who smiles and vocalizes back helps clarify the relation between self and social world. The contrast between these experiences helps young infants sense that they are separate from external reality. Furthermore, 18-month-olds who often establish joint attention with caregivers are advanced in explicit self-awareness, attaining mirror self-recognition at an earlier-than-expected age (Nichols, Fox, & Mundy, 2005). Joint attention offers toddlers many opportunities to compare their own and others' reactions to objects and events, which may enhance their awareness of their own physical uniqueness.

Cultural variations exist in early self-development. In one investigation, urban middle-SES German and East Indian toddlers attained mirror self-recognition earlier than toddlers of non-Western farming communities, such as the Nso people of rural Cameroon and rural families of East India (see Figure 6.4 on page 208) (Kärtner et al., 2012). Urban German and, to a

**FIGURE 6.4 Mirror self-recognition at 19 months in four cultures.** Urban middle-SES German and East Indian toddlers, whose mothers emphasized autonomous child-rearing goals, attained mirror self-recognition earlier than Nso toddlers of rural Cameroon and toddlers of rural East India, whose mothers emphasized relational child-rearing goals. (Based on Kärtner et al., 2012.)

lesser extent, urban East Indian mothers placed considerable emphasis on *autonomous child-rearing goals*, including promoting personal talents and interests and expressing one’s own preferences, which strongly predicted earlier mirror self-recognition. In contrast, Nso and East Indian rural mothers valued *relational child-rearing goals*—doing what parents say and sharing with others. In related research, Nso toddlers, though delayed in mirror self-recognition, displayed an earlier capacity to comply with adult requests than did middle-SES urban Greek toddlers, whose mothers encouraged child autonomy (Keller et al., 2004).

**Self-Awareness and Early Emotional and Social Development.** Self-awareness quickly becomes a central part of children’s emotional and social lives. Recall that self-conscious emotions depend on a strengthening sense of self. Self-awareness also leads to first efforts to understand another’s perspective. Older toddlers who have experienced sensitive caregiving draw on their advancing capacity to distinguish what happens to oneself from what happens to others to express first signs of **empathy**—the ability to understand another’s emotional state and *feel with* that person, or respond emotionally in a similar way. For example, they communicate concern when others are distressed and may offer what they themselves find comforting—a hug, a reassuring comment, or a favorite doll or blanket (Hoffman, 2000; Moreno, Klute, & Robinson, 2008).

Finally, the perspective taking that accompanies toddlers’ firmer sense of self enables them to cooperate in resolving disputes over objects and playing games (Caplan et al., 1991). It also leads to clearer awareness of how to upset others. One 18-month-old heard her mother talking to another adult about an older sibling: “Anny is really frightened of spiders” (Dunn, 1989, p. 107). The innocent-looking toddler ran to the bedroom, returned with a toy spider, and pushed it in front of Anny’s face!

## Categorizing the Self

By the end of the second year, language becomes a powerful tool in self-development. Between 18 and 30 months, children develop a **categorical self** as they classify themselves and others on the basis of age (“baby,” “boy,” or “man”), sex (“boy” or “girl”), physical characteristics (“big,” “strong”), and even goodness versus badness (“I a good girl.” “Tommy mean!”) and competencies (“Did it!” “I can’t”) (Stipek, Gralinski, & Kopp, 1990).

Toddlers use their limited understanding of these social categories to organize their own behavior. As early as 17 months, they select and play in a more involved way with toys that are stereotyped for their own gender—dolls and tea sets for girls, trucks and cars for boys. Their ability to label their own gender predicts a sharp rise in these play preferences over the next few months (Zosuls et al., 2009). Then parents encourage gender-typed behavior by responding more positively when toddlers display it (Hines, 2015). As we will see in Chapter 8, gender typing increases dramatically during early childhood.

## Self-Control

Self-awareness also contributes to effortful control, the extent to which children can inhibit impulses, manage negative emotion, and behave in socially acceptable ways. To behave in a self-controlled fashion, children must think of themselves as separate, autonomous beings who can direct their own actions. And they must have the representational and memory capacities to

SW PRODUCTIONS/PHOTODISC GREEN/GETTY IMAGES

This father encourages compliance and the beginnings of self-control. The toddler joins in the task with an eager, willing spirit, which suggests he is adopting the adult’s directive as his own.

## Applying what we Know

### Helping Toddlers Develop Compliance and Self-Control

SUGGESTION	RATIONALE
Respond to the toddler with sensitivity and encouragement.	Toddlers whose parents are sensitive and supportive sometimes actively resist, but they are also more compliant and self-controlled.
Provide advance notice when the toddler must stop an enjoyable activity.	Toddlers find it more difficult to stop a pleasant activity that is already under way than to wait before engaging in a desired action.
Offer many prompts and reminders.	Toddlers' ability to remember and comply with rules is limited; they need continuous adult oversight and patient assistance.
Respond to self-controlled behavior with verbal and physical approval.	Praise and hugs reinforce appropriate behavior, increasing the likelihood that it will occur again.
Encourage selective and sustained attention (see Chapter 5, pages 161–162).	Development of attention is related to self-control. Children who can shift attention from a captivating stimulus and focus on a less attractive alternative are better at controlling their impulses.
Support language development (see Chapter 5, pages 178–179).	In the second year, children begin to use language to remind themselves of adult expectations and to delay gratification.
Gradually increase rules in a manner consistent with the toddler's developing capacities.	As cognition and language improve, toddlers can follow more rules related to safety, respect for people and property, family routines, manners, and simple chores.

recall a caregiver's directive ("Caitlin, don't touch that light socket!") and apply it to their own behavior.

As these capacities emerge between 12 and 18 months, toddlers first become capable of **compliance**. They show clear awareness of caregivers' wishes and expectations and can obey simple requests and commands. And as every parent knows, they can also decide to do just the opposite! But for most, assertiveness and opposition occur alongside compliance with an eager, willing spirit, which suggests that the child is beginning to adopt the adult's directives as his own (Dix et al., 2007; Kochanska, Murray, & Harlan, 2000). Compliance quickly leads to toddlers' first consciencelike verbalizations—for example, correcting the self by saying "No, can't" before reaching for a cookie or jumping on the sofa.

Researchers often study the early emergence of self-control by giving children tasks that, like the situations just mentioned, require **delay of gratification**—waiting for an appropriate time and place to engage in a tempting act. Between ages 1½ and 4, children show an increasing capacity to wait before eating a treat, opening a present, or playing with a toy (Cole, LeDonne, & Tan, 2013; Vaughn, Kopp, & Krakow, 1984). Children who are advanced in development of attention, language, and suppressing negative emotion tend to be better at delaying gratification—findings that help explain why girls are typically more self-controlled than boys (Else-Quest, 2012).

Like effortful control in general, young children's capacity to delay gratification is influenced by quality of caregiving. Toddlers and preschoolers who experience parental warmth and encouragement are more likely to be cooperative and to resist temptation. Such parenting—which models patient, nonimpulsive behavior—is particularly important for emotionally reactive children (Kochanska, Aksan, & Carlson, 2005; Kochanska & Kim, 2014). Turn back to page 195, and note how these findings

provide yet another example of the importance of goodness of fit between temperament and child rearing.

As self-control improves, parents gradually expand the rules they expect toddlers to follow, from safety and respect for property and people to family routines, manners, and simple chores (Gralinski & Kopp, 1993). Still, toddlers' control over their own actions depends on constant parental oversight and reminders. Several prompts ("Remember, we're going to go in just a minute") and gentle insistence were usually necessary to get Caitlin to stop playing so that she and her parents could go on an errand. Applying What We Know above summarizes ways to help toddlers develop compliance and self-control.

As the second year of life drew to a close, Carolyn, Monica, and Vanessa were delighted at their children's readiness to learn the rules of social life. As we will see in Chapter 8, advances in cognition and language, along with parental warmth and reasonable demands for maturity, lead preschoolers to make tremendous strides in this area.

## Ask yourself

**CONNECT** What type of early parenting fosters the development of emotional self-regulation, secure attachment, and self-control? Why, in each instance, is it effective?

**APPLY** Len, a caregiver of 1- and 2-year-olds, wonders whether toddlers recognize themselves. List signs of self-recognition in the second year that Len can observe.

**REFLECT** In view of research on toddlers' compliance, active resistance, and budding capacity to delay gratification, do you think that the expression "the terrible twos"—commonly used to characterize toddler behavior—is an apt description? Explain.

## Summary / chapter 6

### Erikson's Theory of Infant and Toddler Personality (p. 184)

#### 6.1 What personality changes take place during Erikson's stages of basic trust versus mistrust and autonomy versus shame and doubt?

- Warm, responsive caregiving leads infants to resolve Erikson's psychological conflict of **basic trust versus mistrust** on the positive side.
- During toddlerhood, **autonomy versus shame and doubt** is resolved favorably when parents provide appropriate guidance and reasonable choices. Adjustment problems may emerge if in the first few years children do not establish adequate trust and autonomy.

© SYRACUSE NEWSPAPERS/  
S. CANNERELLI/THE IMAGE WORKS

### Emotional Development (p. 184)

#### 6.2 Describe the development of basic emotions over the first year, noting the adaptive function of each.

- During the first half-year, **basic emotions** gradually become clear, well-organized signals. The **social smile** appears between 6 and 10 weeks, laughter around 3 to 4 months. Happiness strengthens the parent-child bond and both reflects and supports motor, cognitive, and social competencies.
- Anger and fear, especially in the form of **stranger anxiety**, increase in the second half-year as infants' cognitive and motor skills improve. Newly mobile babies use the familiar caregiver as a **secure base** from which to explore.

#### 6.3 Summarize changes during the first two years in understanding others' emotions, expression of self-conscious emotions, and emotional self-regulation.

- The ability to understand others' emotional expressions improves over the first year. At 8 to 10 months, infants engage in **social referencing**. By the middle of the second year, toddlers realize that others' emotional reactions may differ from their own, and they use social referencing to gather information about others' intentions and preferences.
- During toddlerhood, self-awareness and adult instruction provide the foundation for **self-conscious emotions**: guilt, shame, embarrassment, envy, and pride. **Emotional self-regulation** emerges as the prefrontal cortex functions more effectively, as caregivers build on infants' increasing tolerance for stimulation, and as infants' ability to shift attention improves. When caregivers are emotionally sympathetic but set limits, toddlers develop more effective anger-regulation strategies in the preschool years.

### Temperament and Development (p. 190)

#### 6.4 What is temperament, and how is it measured?

- Children differ greatly in **temperament**—early-appearing, stable individual differences in reactivity and self-regulation. The pioneering New York Longitudinal Study identified three patterns: the **easy child**, the **difficult child**, and the **slow-to-warm-up child**. Today, the most influential model of temperament includes dimensions representing emotion, attention, and action, along with **effortful control**, the ability to regulate one's reactivity.
- Temperament is assessed through parental reports, behavior ratings by others familiar with the child, and laboratory observations. Most neurobiological research has focused on distinguishing **inhibited**, or **shy**, children from **uninhibited**, or **sociable**, children.

#### 6.5 Discuss the roles of heredity and environment in the stability of temperament, including the goodness-of-fit model.

- Temperament has low to moderate stability: It develops with age and can be modified by experience. Long-term prediction from early temperament is best achieved after age 3, when children improve substantially in effortful control.

- Ethnic and gender differences in temperament may have genetic foundations but are promoted by cultural beliefs and practices.
- Temperament affects differential susceptibility to rearing experiences. Children with the short 5-HTTLPR genotype, which heightens risk of self-regulation difficulties, function worse than other children when exposed to inept parenting and benefit most from good parenting. Parents tend to emphasize temperamental differences between siblings.
- According to the **goodness-of-fit model**, child-rearing conditions that recognize the child's temperament while encouraging more adaptive functioning promote favorable adjustment.

### Development of Attachment (p. 196)

#### 6.6 Describe the development of attachment during the first two years.

- **Ethological theory**, the most widely accepted perspective on **attachment**, recognizes the infant's emotional tie to the caregiver as an evolved response that promotes survival. In early infancy, built-in signals help bring infants into close contact with other humans. Soon they communicate more freely and quiet more quickly to a familiar caregiver than a stranger.

NINA LEENTIME LIFE PICTURES/GETTY IMAGES

- Around 6 to 8 months, **separation anxiety** and use of the caregiver as a secure base indicate the existence of a true attachment bond. As representation and language develop, separation protest declines. From early caregiving experiences, children construct an **internal working model** that guides future close relationships.

### 6.7 How do researchers measure attachment security, what factors affect it, and what are its implications for later development?

- Using the **Strange Situation**, a laboratory technique for assessing the quality of attachment between 1 and 2 years of age, researchers have identified four attachment patterns: **secure**, **insecure–avoidant**, **insecure–resistant**, and **disorganized/disoriented attachment**. The **Attachment Q-Sort**, based on home observations of children between ages 1 and 5, yields a score ranging from low to high in security.
- Securely attached babies in middle-SES families with favorable life conditions more often maintain their attachment pattern than insecure babies. The disorganized/disoriented pattern shows greater stability than the other patterns. Cultural conditions must be considered in interpreting attachment patterns.

- Attachment security is influenced by early availability of a consistent caregiver, quality of caregiving, the fit between the baby's temperament and parenting practices, and family circumstances. **Sensitive caregiving** is moderately related to secure attachment.

- In Western cultures, **interactional synchrony** characterizes the experiences of securely attached babies. In non-Western village communities and Asian cultures, sensitive caregiving keeps the baby close and dampens emotional expressiveness.
- Continuity of caregiving is the crucial factor determining whether attachment security is linked to later development. If caregiving improves, children can recover from an insecure attachment history.

### 6.8 Describe infants' capacity for multiple attachments.

- Infants develop strong affectionate ties to fathers, who tend to engage in more exciting, physical play with babies than mothers do.
- Early in the first year, infants begin to build rich emotional relationships with siblings that combine rivalry and resentment with affection and sympathetic concern. Individual differences in quality of sibling relationships are influenced by temperament, parenting, and marital quality.

### Self-Development (p. 206)

#### 6.9 Describe the development of self-awareness in infancy and toddlerhood, along with the emotional and social capacities it supports.

- At birth, infants sense that they are physically distinct from their surroundings, an implicit self-awareness that expands during the first few months. In the middle of the second year, explicit awareness of the self's physical features emerges. Around age 2, **self-recognition** is clearly evident as toddlers identify themselves in photos and by name. However, **scale errors**, attempting to do things that their body size makes impossible, are common at this age.

SW PRODUCTIONS/PHOTODISC GREEN/GETTY IMAGES

- Self-awareness also contributes to self-control. **Compliance** emerges between 12 and 18 months, followed by **delay of gratification**, which strengthens between 1½ and 4 years. Children who experience parental warmth and gentle encouragement are likely to be advanced in self-control.

## Important Terms and Concepts

attachment (p. 196)  
 Attachment Q-Sort (p. 198)  
 autonomy versus shame and doubt (p. 184)  
 basic emotions (p. 185)  
 basic trust versus mistrust (p. 184)  
 categorical self (p. 208)  
 compliance (p. 209)  
 delay of gratification (p. 209)  
 difficult child (p. 190)  
 disorganized/disoriented attachment (p. 198)  
 easy child (p. 190)  
 effortful control (p. 191)

emotional self-regulation (p. 189)  
 empathy (p. 208)  
 ethological theory of attachment (p. 196)  
 goodness-of-fit model (p. 195)  
 inhibited, or shy, child (p. 191)  
 insecure–avoidant attachment (p. 198)  
 insecure–resistant attachment (p. 198)  
 interactional synchrony (p. 200)  
 internal working model (p. 197)  
 scale errors (p. 207)  
 secure attachment (p. 198)  
 secure base (p. 186)

self-conscious emotions (p. 188)  
 self-recognition (p. 207)  
 sensitive caregiving (p. 207)  
 separation anxiety (p. 197)  
 slow-to-warm-up child (p. 190)  
 social referencing (p. 188)  
 social smile (p. 185)  
 stranger anxiety (p. 186)  
 Strange Situation (p. 197)  
 temperament (p. 190)  
 uninhibited, or sociable, child (p. 191)

# milestones

## Development in Infancy and Toddlerhood

ELECTRA K. VASILEADOU/GETTY

### BIRTH–6 MONTHS

#### Physical

- Height and weight increase rapidly. (116)
- Newborn reflexes decline. (101–103)
- Distinguishes basic tastes and odors; prefers sweet-tasting foods. (108)
- Responses can be classically and operantly conditioned. (130–131)
- Habituates to unchanging stimuli; recovers to novel stimuli. (131–132)
- Sleep is increasingly organized into a night-day schedule. (125)
- Holds head up, rolls over, and grasps objects. (134, 136)
- Perceives auditory and visual stimuli as organized patterns. (138, 140, 141–142)
- Shows sensitivity to motion, then binocular, and finally pictorial depth cues. (140–141)
- Recognizes and prefers human facial pattern; recognizes features of mother's face. (143)
- Masters a wide range of intermodal (visual, auditory, and tactile) relationships. (144)

#### Cognitive

- Engages in immediate and deferred imitation of adults' facial expressions. (132–133, 154)
- Repeats chance behaviors that lead to pleasurable and interesting results. (151–152)
- Has some awareness of many physical properties (including object permanence) and basic numerical knowledge. (153–154, 158–159)

- Visual search behavior and recognition memory for visual events improve. (161, 162)
- Attention becomes more efficient and flexible. (161)
- Forms categories for familiar objects based on similar physical properties. (163–164)

#### Language

- Coos and, by end of this period, babbles. (175)
- Begins to establish joint attention with caregiver, who labels objects and events. (176)
- By end of this period, comprehends some word meanings. (176)

#### Emotional/Social

- Social smile and laughter emerge. (185)
- Matches feeling tone of caregiver in face-to-face communication; later, expects matched responses. (188)

TETRA IMAGES/ALAMY

- Distinguishes positive from negative emotion in voices and facial expressions. (188)
- Emotional expressions become well-organized and meaningfully related to environmental events. (185)
- Regulates emotion by shifting attention and self-soothing. (189)
- Smiles, laughs, and babbles more to caregiver than to a stranger. (197)
- Awareness of self as physically distinct from surroundings increases. (207)

### 7–12 MONTHS

#### Physical

- Approaches adultlike sleep-wake schedule. (125)
- Sits alone, crawls, and walks. (134)

LAURA DWIGHT PHOTOGRAPHY

- Reaching and grasping improve in flexibility and accuracy; shows refined pincer grasp. (137)
- Discriminates among a wider range of facial expressions, including happiness, surprise, sadness, fearfulness, and anger. (143)

#### Cognitive

- Engages in intentional, or goal-directed, behavior. (152)
- Finds object hidden in an initial location. (152)
- Recall memory improves, as indicated by gains in deferred imitation of adults' actions with objects. (154–155, 163)
- Tool use in problem solving emerges; solves simple problems by analogy to a previous problem. (155)
- Categorizes objects on the basis of subtle sets of features, even when the perceptual contrast between categories is minimal. (164)

ELLEN B. SEMISI

Note: Numbers in parentheses indicate the page or pages on which each milestone is discussed.

## Language

- Babbling expands to include many sounds of spoken languages and patterns of the child's language community. (176)
- Joint attention with caregiver becomes more accurate. (176)
- Takes turns in games, such as pat-a-cake and peekaboo. (176)
- Uses preverbal gestures (showing, pointing) to influence others' behavior and convey information. (176)
- Around end of this period, understands displaced reference of words and says first words. (155–156, 177)

## Emotional/Social

- Smiling and laughter increase in frequency and expressiveness. (185)
- Anger and fear increase in frequency and intensity. (185)
- Stranger anxiety and separation anxiety appear. (186, 197)
- Uses caregiver as a secure base for exploration. (186)
- Shows “clear-cut” attachment to familiar caregivers. (197)
- Increasingly detects the meaning of others' emotional expressions and engages in social referencing. (188)
- Regulates emotion by approaching and retreating from stimulation. (189)

## 13–18 MONTHS

### Physical

- Height and weight gain are rapid, but not as great as in first year. (117)
- Walking is better coordinated. (135–136)
- Manipulates small objects with improved coordination. (137)

### Cognitive

- Explores the properties of objects by acting on them in novel ways. (152)
- Searches in several locations for a hidden object. (152)
- Engages in deferred imitation of adults' actions with objects over longer delays and across a change in context—for example, from child care to home. (154–155)
- Sustained attention increases. (161–162)
- Recall memory improves further. (163)
- Sorts objects into categories. (164)
- Realizes that pictures can symbolize real objects. (156)

LAURA DWIGHT PHOTOGRAPHY

## Language

- Steadily adds to vocabulary. (175, 177)
- By end of this period, produces 50 words. (175)

## Emotional/Social

- Realizes that others' emotional reactions may differ from one's own. (188)

DREAMPICTURES/VANESSA GAVALYA

- Complies with simple directives. (209)

## 19–24 MONTHS

### Physical

- Walks up stairs with help, jumps, and walks on tiptoe. (134)
- Manipulates small objects with good coordination. (137)

### Cognitive

- Solves simple problems suddenly, through representation. (152)
- Finds a hidden object that has been moved while out of sight. (152)
- Engages in make-believe play, using simple actions experienced in everyday life. (153, 168)

LAURA DWIGHT PHOTOGRAPHY

- Engages in deferred imitation of actions an adult tries to produce, even if not fully realized. (155)
- Categorizes objects conceptually, on the basis of common function or behavior. (164–165)
- Begins to use language as a flexible symbolic tool to modify existing mental representations. (156)

## Language

- Produces 200 to 250 words. (175)
- Combines two words. (177)

## Emotional/Social

- Self-conscious emotions (shame, embarrassment, guilt, envy, and pride) emerge. (188–189)
- Acquires a vocabulary for talking about feelings. (189)
- Begins to use language to assist with emotional self-regulation. (189–190)
- Begins to tolerate caregiver's absences more easily; separation anxiety declines. (197)
- Recognizes image of self and, by end of this period, uses own name or personal pronoun to refer to self. (207)
- Shows signs of empathy. (208)

LAURA DWIGHT PHOTOGRAPHY

- Categorizes self and others on the basis of age, sex, physical characteristics, and goodness and badness. (208)

## Physical and Cognitive Development in Early Childhood

On an outing with 3- and 4-year-olds to a city pond, a teacher points out features of goldfish and responds to children's observations and questions. Language and knowledge of the world expand rapidly in early childhood, supported by rich conversations with adults and peers.

For more than a decade, my fourth-floor office window overlooked the preschool and kindergarten play yard of our university laboratory school. On mild fall and spring mornings, classroom doors swung open, and sand table, easels, and large blocks spilled out into a small courtyard. Alongside the building was a grassy area with jungle gyms, swings, a play-house, and a flower garden planted by the children; beyond it, a circular path lined with tricycles and wagons. Each day, the setting was alive with activity.

The years from 2 to 6 are often called “the play years,” since play blossoms during this time, becoming increasingly complex, flexible, and symbolic. Our discussion opens with the physical attainments of this period—body and brain growth and improvements in motor coordination. We pay special attention to genetic and environmental factors that support these changes and to their intimate connection with other domains of development.

Then we explore early childhood cognition, beginning with Piaget's preoperational stage. Recent research, along with Vygotsky's socio-cultural theory and information processing, extends our understanding of preschoolers' cognitive competencies. Next, we address

factors that contribute to individual differences in mental development—the home environment, the quality of preschool and child care, and the many hours young children devote to television, computers, and other electronic media. We conclude with the dramatic expansion of language in early childhood. ●

## PHYSICAL DEVELOPMENT

### A Changing Body and Brain

**7.1** Describe body growth and brain development during early childhood.

In early childhood, the rapid increase in body size of the first two years tapers off. On average, children add 2 to 3 inches in height and about 5 pounds in weight each year. Boys continue to be

slightly larger than girls. As “baby fat” drops off further, children gradually become thinner, although girls retain somewhat more body fat than boys, who are slightly more muscular. As Figure 7.1 shows, by age 5 the top-heavy, bowlegged, potbellied toddler has become a more streamlined, flat-tummied, longer-legged child with body proportions similar to those of adults. Consequently, posture and balance improve—changes that support gains in motor coordination.

Individual differences in body size are even more apparent during early childhood than in infancy and toddlerhood. Speeding around the bike path in the play yard, 5-year-old Darryl—at 48 inches tall and 55 pounds—towered over his kindergarten

**FIGURE 7.1** Body growth during early childhood. During the preschool years, children grow more slowly than in infancy and toddlerhood. Wilson's and Mariel's bodies became more streamlined, flat-tummied, and longer-legged. Boys continue to be slightly taller, heavier, and more muscular than girls. But generally, the two sexes are similar in body proportions and physical capacities.

classmates. (The average North American 5-year-old boy is 43 inches tall and weighs 42 pounds.) Priti, an Asian-Indian child, was unusually small because of genetic factors linked to her cultural ancestry. Hal, a European-American child from a poverty-stricken home, was well below average for reasons we will discuss shortly.

## Skeletal Growth

The skeletal changes of infancy continue throughout early childhood. Between ages 2 and 6, approximately 45 new *epiphyses*, or growth centers in which cartilage hardens into bone, emerge in various parts of the skeleton. X-rays of these growth centers enable doctors to estimate children's *skeletal age*, or progress toward physical maturity (see page 117 in Chapter 4)—information helpful in diagnosing growth disorders.

By the end of the preschool years, children start to lose their primary, or “baby,” teeth. The age at which they do so is heavily influenced by heredity. For example, girls, who are ahead of boys in physical development, lose their primary teeth earlier. Environmental influences also matter: Prolonged malnutrition delays the appearance of permanent teeth, whereas overweight and obesity accelerate it (Costacurta et al., 2012; Heinrich-Weltzien et al., 2013).

Diseased baby teeth can affect the health of permanent teeth, so preventing decay in primary teeth is essential—by brushing consistently, avoiding sugary foods, drinking fluoridated water, and getting topical fluoride treatments and sealants (plastic coatings that protect tooth surfaces). Another factor is exposure to tobacco smoke, which suppresses children's immune system, including the ability to fight bacteria responsible for tooth decay. Young children in homes with regular smokers are at increased risk for decayed teeth (Hanioka et al., 2011).

An estimated 23 percent of U.S. preschoolers have tooth decay, a figure that rises to 50 percent in middle childhood and 60 percent by age 18. Causes include poor diet and inadequate health care—factors that are more likely to affect low-SES children. One-third of U.S. children living in poverty have untreated dental caries (Centers for Disease Control and Prevention, 2015e).

## Brain Development

Between ages 2 and 6, the brain increases from 70 percent of its adult weight to 90 percent. At the same time, preschoolers improve in a wide variety of skills—physical coordination, perception, attention, memory, language, logical thinking, and imagination.

By age 4 to 5, many parts of the cerebral cortex have overproduced synapses. In some regions, such as the prefrontal cortex, the number of synapses is nearly double the adult value. Together, synaptic growth and myelination of neural fibers result in a high energy need. In fact, fMRI evidence reveals that energy metabolism in the cerebral cortex peaks around this age (Nelson, Thomas, & de Haan, 2006). *Synaptic pruning* follows: Neurons

© STANISLAV SOLINTSEV/13/OCEAN/CORBIS

Genetic influences and parental acceptance may have contributed to this 5-year-old's left-handedness. Left-handed individuals show certain cognitive advantages, perhaps because their brains are less strongly lateralized than those of right-handers.

that are seldom stimulated lose their connective fibers, and the number of synapses gradually declines. By age 8 to 10, energy consumption of most cortical regions diminishes to near-adult levels (Lebel & Beaulieu, 2011). And cognitive capacities increasingly localize in distinct neural systems that become interconnected, resulting in networks of coordinated neural functioning that support children's advancing abilities (Bathelt et al., 2013; Markant & Thomas, 2013).

EEG, NIRS, and fMRI measures of neural activity reveal especially rapid growth from early to middle childhood in prefrontal-cortical areas devoted to various aspects of executive function: inhibition, working memory, flexibility of thinking, and planning—capacities that advance markedly over the preschool years (Müller & Kerns, 2015). Furthermore, for most children, the left cerebral hemisphere is especially active between 3 and 6 years and then levels off. In contrast, activity in the right hemisphere increases steadily throughout early and middle childhood (Thatcher, Walker, & Giudice, 1987).

These findings fit nicely with what we know about several aspects of cognitive development. Language skills (typically housed in the left hemisphere) expand at an astonishing pace in early childhood, and they support children's improved executive function. In contrast, spatial skills (usually located in the right hemisphere), such as giving directions, drawing pictures, and recognizing geometric shapes, develop gradually over childhood and adolescence.

Differences in rate of development between the two hemispheres suggest that they are continuing to *lateralize* (specialize in cognitive functions). Let's take a closer look at brain lateralization in early childhood by focusing on handedness.

**Handedness.** Research on handedness, along with other evidence covered in Chapter 4, supports the joint contribution of nature and nurture to brain lateralization. By age 6 months, infants typically display a smoother, more efficient movement

when reaching with their right than their left arm—an early tendency that may contribute to the right-handed bias of most children by the end of the first year (Nelson, Campbell, & Michel, 2013; Rönnqvist & Domellöf, 2006). Gradually, handedness extends to additional skills.

Handedness reflects the greater capacity of one side of the brain—the individual's **dominant cerebral hemisphere**—to carry out skilled motor action. Other important abilities are generally located on the dominant side as well. For right-handed people—in Western nations, 90 percent of the population—language is housed in the left hemisphere with hand control. For the left-handed 10 percent, language is occasionally located in the right hemisphere or, more often, shared between the hemispheres (Szaflarski et al., 2012). This indicates that the brains of left-handers tend to be less strongly lateralized than those of right-handers.

Heritability of left-handedness is weak to modest: Left-handed parents have only a mildly elevated chance of having left-handed children (Somers et al., 2015; Suzuki & Ando, 2014). This suggests a genetic *bias* favoring right-handedness that experiences can overcome, swaying children toward a left-hand preference.

Handedness involves practice. It is strongest for complex skills requiring extensive training, such as eating with utensils, writing, and engaging in athletic activities. And wide cultural differences exist. For example, in tribal and village cultures, rates of left-handedness are relatively high. But in a study of one such society in New Guinea, individuals who had attended school in childhood were far more likely to be extremely right-handed—findings that highlight the role of experience (Geuze et al., 2012).

Although left-handedness is elevated among people with intellectual disabilities and mental illness, atypical brain lateralization is probably not responsible for these individuals' problems. Rather, early damage to the left hemisphere may have caused their disabilities while also leading to a shift in handedness. In support of this idea, left-handedness is associated with prenatal and birth difficulties that can result in brain damage, including maternal stress, prolonged labor, prematurity, Rh incompatibility, and breech delivery (Domellöf, Johansson, & Rönnqvist, 2011; Kurganskaya, 2011).

Most left-handers, however, have no developmental problems. In fact, left- and mixed-handed young people are slightly advantaged in speed and flexibility of thinking, and they are more likely than their right-handed agemates to develop outstanding verbal and mathematical talents (Beratis et al., 2013; Noroozian et al., 2012). More even distribution of cognitive functions across both brain hemispheres may be responsible.

**Other Advances in Brain Development.** Besides the cerebral cortex, several other areas of the brain make strides during early childhood (see Figure 7.2). All of these changes involve establishing links between parts of the brain, increasing the coordinated functioning of the central nervous system.

**FIGURE 7.2** Cross-section of the human brain, showing the location of the cerebellum, the reticular formation, the amygdala, the hippocampus, and the corpus callosum. These structures undergo considerable development during early childhood. Also shown is the pituitary gland, which secretes hormones that control body growth (see page 219).

At the rear and base of the brain is the **cerebellum**, a structure that aids in balance and control of body movement. Fibers linking the cerebellum to the cerebral cortex grow and myelinate from birth through the preschool years, contributing to dramatic gains in motor coordination: By the end of the preschool years, children can play hopscotch, throw and catch a ball with well-coordinated movements, and print letters of the alphabet. Connections between the cerebellum and cerebral cortex also support thinking (Diamond, 2000). Children with damage to the cerebellum usually display both motor and cognitive deficits, including problems with memory, planning, and language (Hoang et al., 2014; Noterdaeme et al., 2002).

The **reticular formation**, a structure in the brain stem that maintains alertness and consciousness, generates synapses and myelinates from infancy into the twenties (Sampaio & Truwit, 2001). Neurons in the reticular formation send out fibers to other brain regions. Many go to the prefrontal cortex, contributing to improvements in sustained, controlled attention.

An inner brain structure called the **amygdala** plays a central role in processing of novelty and emotional information. The amygdala is sensitive to facial emotional expressions, especially fear (Adolphs, 2010). It also enhances memory for emotionally salient events, thereby ensuring that information vital for survival—stimuli that signify danger or safety—will be retrieved on future occasions. Throughout childhood and adolescence, connections between the amygdala and the prefrontal cortex, which governs regulation of emotion, form and myelinate (Tottenham, Hare, & Casey, 2009).

Also located in the inner-brain, adjacent to the amygdala, is the **hippocampus**, which plays a vital role in memory and in images of space that help us find our way, undergoes rapid

This child has been diagnosed with a rare condition in which part of the corpus callosum is absent. He has difficulty with tasks that have multiple steps and that require coordinated movements on both sides of the body. Here, a therapist helps him learn to tie shoes.

synapse formation and myelination in the second half of the first year, when recall memory and independent movement emerge. Over the preschool and elementary school years, the hippocampus and surrounding areas of the cerebral cortex continue to develop swiftly, establishing connections with one another and with the prefrontal cortex and lateralizing toward greater right-sided activation (Hopf et al., 2013; Nelson, Thomas, & de Haan, 2006). These changes support the dramatic gains in memory and spatial understanding of early and middle childhood.

The **corpus callosum** is a large bundle of fibers connecting the two cerebral hemispheres. Production of synapses and myelination of the corpus callosum peak between 3 and 6 years, continuing at a slower pace through adolescence (Thompson et al., 2000). The corpus callosum supports smooth coordination of movements on both sides of the body and integration of many aspects of thinking, including perception, attention, memory, language, and problem solving. The more complex the task, the more essential is communication between the hemispheres.

## Influences on Physical Growth and Health

**7.2** Describe the effects of heredity, nutrition, and infectious disease on physical growth and health in early childhood.

**7.3** What factors increase the risk of unintentional injuries, and how can childhood injuries be prevented?

As we consider factors affecting growth and health in early childhood, you will encounter some familiar themes. Heredity remains important, but good nutrition, relative freedom from disease, and physical safety are also essential.

## Heredity and Hormones

The impact of heredity on physical growth is evident throughout childhood. Children's physical size and rate of growth are related to those of their parents (Bogin, 2001). Genes influence growth by controlling the body's production of hormones. Figure 7.2 on page 218 shows the **pituitary gland**, located at the base of the brain, which plays a crucial role by releasing two hormones that induce growth.

The first, **growth hormone (GH)**, is necessary for development of almost all body tissues. Without medical intervention, children who lack GH reach an average mature height of only 4 to 4½ feet. When treated early with injections of GH, such children show catch-up growth and then grow at a normal rate, becoming much taller than they would have without treatment (Bright, Mendoza, & Rosenfeld, 2009).

A second pituitary hormone, **thyroid-stimulating hormone (TSH)**, prompts the thyroid gland in the neck to release *thyroxine*, which is necessary for brain development and for GH to have its full impact on body size. Infants born with inadequate thyroxine must receive it at once, or they will be intellectually disabled. Once the most rapid period of brain development is complete, children with too little thyroxine grow at a below-average rate, but the central nervous system is no longer affected (Donaldson & Jones, 2013). With prompt treatment, such children catch up in body growth and eventually reach normal size (Høybe et al., 2015).

## Nutrition

With the transition to early childhood, many children become unpredictable, picky eaters. One father I know wistfully recalled how his son, as a toddler, eagerly sampled Chinese food: “Now, at age 3, the only thing he’ll try is the ice cream!”

Preschoolers' appetites decline because their growth has slowed. And their wariness of new foods is adaptive. If they stick to familiar foods, they are less likely to swallow dangerous substances when adults are not around to protect them. With the transition to middle childhood, picky eating usually subsides (Birch & Fisher, 1995; Cardona Cano et al., 2015).

Though they eat less, preschoolers require a high-quality diet, including the same nutrients adults need, but in smaller quantities. Fats, oils, salt, and sugar should be kept to a minimum because of their link to high blood pressure and heart disease in adulthood. And foods high in sugar should be eaten sparingly to prevent tooth decay and overweight and obesity—a topic we will take up in Chapter 9.

Children tend to imitate the food choices of people they admire, both adults and peers. For example, in Mexico, where children often see family members enjoying peppery foods, preschoolers enthusiastically eat chili peppers, whereas most U.S. children reject them (Birch, Zimmerman, & Hind, 1980). Repeated, unpressured exposure to new foods also promotes acceptance (Lam, 2015). For example, serving broccoli or tofu increases children's liking for these healthy foods. In contrast,

© ADAM HESTER/CORBIS

This Mexican 3-year-old helps his mother prepare refried beans for dinner. Children tend to imitate the food preferences of those they admire—both adults and peers.

offering sweet fruit drinks or soft drinks promotes “milk avoidance” (Black et al., 2002).

Although children’s healthy eating depends on a wholesome food environment, offering bribes—“Finish your vegetables, and you can have an extra cookie”—leads children to like the healthy food less and the treat more (Birch, Fisher, & Davison, 2003). In general, coercing children to eat results in withdrawal from food, whereas food restriction leads to excessive eating. In a study of nearly 5,000 Dutch 4-year-olds, the more mothers reported pressuring their child to eat, the greater the likelihood of an underweight child. And the more mothers reported restricting their child’s eating, the greater the chances of an overweight or obese child (see Figure 7.3) (Jansen et al., 2012).

### LOOK and LISTEN

Arrange to join a family with at least one preschooler for a meal, and closely observe parental mealtime practices. Are they likely to promote healthy eating habits? Explain.

Finally, as indicated in earlier chapters, many children in the United States and in developing countries lack access to sufficient high-quality food to support healthy growth. Five-year-old Hal rode a bus from a poor neighborhood to our laboratory preschool. His mother’s welfare check barely covered her rent, let alone food. Hal’s diet was deficient in protein and in essential vitamins and minerals—iron (to prevent anemia), calcium (to support development of bones and teeth), zinc (to support immune system functioning, neural communication, and cell duplication), vitamin A (to help maintain eyes, skin, and a variety of internal organs), and vitamin C (to facilitate iron absorption and wound healing). These are the most common dietary deficiencies of the preschool years (Yousafzai, Yakoob, & Bhutta, 2013).

Hal was small for his age, pale, inattentive, and disruptive at preschool. By the school years, low-SES U.S. children are, on average,  $\frac{1}{2}$  to 1 inch shorter than their economically advantaged counterparts (Cecil et al., 2005). And throughout childhood and

**FIGURE 7.3 Relationship of maternal feeding practices to underweight, overweight, and obesity among preschoolers.** In a Dutch study of nearly 5,000 4-year-olds, mothers who pressured their child to eat were more likely to have an underweight child. Mothers who restricted their child’s eating increased their chances of having an overweight or obese child. These relationships held even after controlling for many factors that could have influenced maternal feeding practices and preschoolers’ weight gain, including parents’ SES, ethnicity, height and weight, and children’s enjoyment of eating. (Based on Jansen et al., 2012.)

adolescence, a nutritionally deficient diet is associated with attention and memory difficulties, poorer intelligence and achievement test scores, and behavior problems—especially hyperactivity and aggression—even after family factors that might account for these relationships are controlled (Liu et al., 2004; Lukowski et al., 2010).

## Infectious Disease

One day, I noticed that Hal had been absent from the play yard for several weeks, so I asked Leslie, his preschool teacher, what was wrong. “Hal’s been hospitalized with the measles,” she explained. “He’s had difficulty recovering—lost weight when there wasn’t much to lose in the first place.” In well-nourished children, ordinary childhood illnesses have no effect on physical growth. But when children are undernourished, disease interacts with malnutrition in a vicious spiral, with potentially severe consequences.

**Infectious Disease and Malnutrition.** Hal’s reaction to the measles is commonplace in developing countries, where a large proportion of the population lives in poverty and many children do not receive routine immunizations. Illnesses such as measles and chickenpox, which typically do not appear until after age 3 in industrialized nations, occur much earlier. Poor diet depresses the body’s immune system, making children far more susceptible to disease. Of the 5.9 million annual deaths of children under age 5 worldwide, 98 percent are in developing countries and about half are due to infectious diseases (World Health Organization, 2015d).

Disease, in turn, is a major contributor to malnutrition, hindering both physical growth and cognitive development. Illness reduces appetite and limits the body's ability to absorb foods, especially in children with intestinal infections. In developing countries, widespread diarrhea, resulting from unsafe water and contaminated foods, leads to growth stunting and an estimated 1 million childhood deaths each year (Unger et al., 2014). Studies carried out in the slums and shantytowns of Brazil and Peru reveal that the more persistent diarrhea is in early childhood, the shorter children are in height and the lower their intelligence test scores during the school years (Checkley et al., 2003; Lorntz et al., 2006).

Most developmental impairments and deaths due to diarrhea can be prevented with nearly cost-free *oral rehydration therapy (ORT)*, in which sick children are given a glucose, salt, and water solution that quickly replaces fluids the body loses. Since 1990, public health workers have taught nearly half the families in the developing world how to administer ORT. Also, low-cost supplements of zinc (essential for immune system functioning) substantially reduce the incidence of severe and prolonged diarrhea, especially when combined with ORT (Galvao et al., 2013).

**Immunization.** In industrialized nations, childhood diseases have declined dramatically during the past half-century, largely as a result of widespread immunization of infants and young children. Hal got the measles because he did not receive a full program of immunizations.

In the United States, routine childhood immunizations have prevented an estimated 322 million illnesses and 700,000 deaths over the past two decades (Whitney et al., 2014). Yet about 17 percent of U.S. preschoolers lack essential immunizations. The rate rises to 22 percent for poverty-stricken children, many of whom do not receive full protection until age 5 or 6, when it is required for school entry (Centers for Disease Control and Prevention, 2015j). In contrast, fewer than 10 percent of preschoolers lack immunizations in Australia, Denmark, and Norway, and fewer than 5 percent in Canada, the Netherlands, Sweden, and the United Kingdom (World Health Organization, 2015b).

Why does the United States lag behind these countries? Although the U.S. Affordable Care Act of 2010 greatly improved health insurance coverage for American children, many low-income children remain without coverage and, therefore, may not receive timely vaccinations. Beginning in 1994, all U.S. children whose parents were unable to pay were guaranteed free immunizations, a program that has led to gains in immunization rates.

But inability to afford vaccines is not the only cause of inadequate immunization. Parents with little education and with stressful daily lives often fail to schedule vaccination appointments, and those without a primary-care physician do not want to endure long waits in crowded U.S. public health clinics (Falagas & Zarkadoulia, 2008). Some parents have been influenced by media reports—now widely discredited—suggesting a link between a mercury-based preservative used for decades in vaccines and a rise in the number of children diagnosed with autism. In fact, large-scale studies show no association with autism and no consistent effects on cognitive performance (Hensley &

Briars, 2010; Richler et al., 2006; Thompson et al., 2007). Still, as a precautionary measure, mercury-free versions of childhood vaccines are now available. Other parents have religious or philosophical objections—for example, the belief that children should develop immunities naturally.

In areas where many parents have refused to immunize their children, outbreaks of whooping cough and rubella have occurred, with life-threatening consequences. Public education programs directed at increasing parental knowledge about the importance and safety of timely immunizations are badly needed. The Netherlands achieves its high child immunization rate by giving parents of every newborn baby a written schedule of when and where the child should be immunized (Lernout et al., 2013). If a parent does not bring the child at the specified time, a public health nurse goes to the home to ensure that the child remains in step with the schedule.

## Childhood Injuries

Unintentional injuries are the leading cause of childhood mortality in industrialized nations. Although U.S. childhood injury fatalities have declined steadily over the past 35 years due to policies aimed at improving child safety, the United States ranks poorly among Western nations in these largely preventable events. About 35 percent of U.S. childhood deaths and 50 percent of adolescent deaths result from injuries, causing over 8,000 children to die annually (Child Trends, 2014c). And among the hundreds of thousands of injured children and youths who survive, many suffer pain, brain damage, and permanent physical disabilities.

Auto and traffic accidents, suffocation, drowning, and poisoning are the most common injuries resulting in childhood deaths (Safe Kids Worldwide, 2015). Motor vehicle collisions are by far the most frequent overall source of injury. They rank as the second leading U.S. cause of mortality from birth to age 5 (after suffocation among infants and drowning among toddlers and preschoolers) and as the leading cause among school-age children and adolescents.

**Factors Related to Childhood Injuries.** The common view of childhood injuries as “accidental” suggests they are due to chance and cannot be prevented. In fact, these injuries occur within a complex *ecological system* of individual, family, community, and societal influences—and we can do something about them.

Because of their higher activity level and greater impulsivity and risk taking, boys are nearly twice as likely as girls to be injured, and their injuries are more severe (Child Trends, 2014c). Children with certain temperamental and personality characteristics—inattentiveness, overactivity, irritability, defiance, and aggression—are also at greater risk (Ordonana, Caspi, & Moffitt, 2008; Schwebel & Gaines, 2007). As we saw in Chapter 6, these children present child-rearing challenges. They are likely to protest when placed in auto seat restraints, to refuse to take a companion's hand when crossing the street, and to disobey even after repeated instruction and discipline.

JEFFA IMAGES/BARCOFT MEDIA/GETTY IMAGES

Childhood injury rates are highest in areas with extensive poverty, lack of high-quality child care, and weak parental vigilance, as illustrated by these children's makeshift playground.

Poverty, single parenthood, and low parental education are also strongly associated with injury (Dudani, Macpherson, & Tamim, 2010; Schwebel & Brezaussek, 2007). Parents who must cope with many daily stresses often have little time or energy to monitor the safety of their children. And their homes and neighborhoods are likely to be noisy, crowded, and rundown, posing further risks.

Broad societal conditions also affect childhood injury. In developing countries, the rate of childhood death from injury is far greater than in developed nations (Kahn et al., 2015). Rapid population growth, overcrowding in cities, and heavy road traffic combined with weak safety measures are major causes. Safety devices, such as car safety seats and bicycle helmets, are neither readily available nor affordable.

Childhood injury rates are high in the United States because of extensive poverty, shortages of high-quality child care (to supervise children in their parents' absence), and a high rate of births to teenagers, who are not ready for parenthood (Child Trends, 2014a; Höllwarth, 2013). But U.S. children from advantaged families are also at considerably greater risk for injury than children in Western Europe. This indicates that besides reducing poverty and teenage pregnancy and upgrading the status of child care, additional steps are needed to ensure children's safety.

**Preventing Childhood Injuries.** Childhood injuries have many causes, so a variety of approaches are needed to reduce them. Laws prevent many injuries by requiring car safety seats, child-resistant caps on medicine bottles, flameproof clothing, and fencing around backyard swimming pools. Communities can help by modifying their physical environments. Playgrounds, a common site of injury, can be covered with protective surfaces. Free, easily installed window guards can be given to families in high-rise apartment buildings to prevent falls. And media campaigns can inform parents and children about safety issues.

But even though they know better, many parents and children behave in ways that compromise safety. About 27 percent of U.S. parents fail to place their children in car safety seats, and nearly 75 percent of infant seats and 40 percent of child booster seats are improperly used (Macy et al., 2015; Safe Kids Worldwide, 2011). American parents, especially, seem willing to ignore familiar safety practices, perhaps because of the high value they place on individual rights and personal freedom.

Furthermore, many parents overestimate young children's knowledge of safety rules, engaging in too little monitoring of their access to hazards. And when parents teach safety rules to preschoolers, they frequently fail to explain the basis for the rules—despite evidence that explanations enhance children's retention, understanding, and compliance (Morrongiello, Ondejko, & Littlejohn, 2004; Morrongiello et al., 2014). Even with well-learned rules, preschoolers need supervision to ensure that they comply (Morrongiello, Midgett, & Shields, 2001).

Interventions aimed at parents that highlight risk factors and that model and reinforce safety practices are effective in reducing home hazards and childhood injuries (Kendrick et al., 2008). Attention must also be paid to family conditions that can prevent childhood injury: relieving crowding in the home, providing social supports to ease parental stress, and teaching parents to use effective discipline—a topic we will take up in Chapter 8.

## Ask yourself

**CONNECT** Using research on handedness, malnutrition, or unintentional injuries, show how physical growth and health in early childhood result from a complex interplay between heredity and environment.

**APPLY** One day, Leslie prepared a new snack to serve at preschool: celery stuffed with ricotta cheese. The first time she served it, few children touched it. How can Leslie encourage her students to accept the snack? What tactics should she avoid?

**REFLECT** Ask a parent or other family member whether, as a preschooler, you were a picky eater, suffered from many infectious diseases, or sustained any serious injuries. What factors might have been responsible?

## Motor Development

**7.4** Cite major milestones of gross- and fine-motor development, along with factors that affect motor progress, in early childhood.

Observe several 2- to 6-year-olds at play in a neighborhood park, preschool, or child-care center. You will see that an explosion of new motor skills occurs in early childhood, each of which builds on the simpler movement patterns of toddlerhood.

During the preschool years, children continue to integrate previously acquired skills into more complex, *dynamic systems*. Then they revise each new skill as their bodies grow larger and stronger, their central nervous systems develop, their environments present new challenges, and they set new goals.

## Gross-Motor Development

As children's bodies become more streamlined and less top-heavy, their center of gravity shifts downward, toward the trunk. As a result, balance improves greatly, paving the way for new motor skills involving large muscles of the body. By age 2, children's gaits become smooth and rhythmic—secure enough that soon they leave the ground, at first by running and later by jumping, hopping, galloping, and skipping.

As children become steadier on their feet, their arms and torsos are freed to experiment with new skills—throwing and catching balls, steering tricycles, and swinging on horizontal bars and rings. Then upper- and lower-body skills combine into more refined actions. Five- and 6-year-olds simultaneously steer and pedal a tricycle and flexibly move their whole body when throwing, catching, hopping, and jumping. By the end of the preschool years, all skills are performed with greater speed and endurance. Table 7.1 provides a closer look at gross-motor development in early childhood.

© ELLEN B. SENISI

As balance improves, preschoolers can combine upper- and lower-body skills into more refined actions, such as walking on stilts.

**TABLE 7.1**  
Changes in Gross- and Fine-Motor Skills During Early Childhood

AGE	GROSS-MOTOR SKILLS	FINE-MOTOR SKILLS
2–3 years	Walks more rhythmically; hurried walk changes to run Jumps, hops, throws, and catches with rigid upper body Pushes riding toy with feet; little steering	Puts on and removes simple items of clothing Zips and unzips large zippers Uses spoon effectively
3–4 years	Walks up stairs, alternating feet, and down stairs, leading with one foot Jumps and hops, flexing upper body Throws and catches with slight involvement of upper body; still catches by trapping ball against chest Pedals and steers tricycle	Fastens and unfastens large buttons Serves self food without assistance Uses scissors Copies vertical line and circle Draws first picture of person, using tadpole image
4–5 years	Walks down stairs, alternating feet Runs more smoothly Gallops and skips with one foot Throws ball with increased body rotation and transfer of weight from one foot to the other; catches ball with hands Rides tricycle rapidly, steers smoothly	Uses fork effectively Cuts with scissors following line Copies triangle, cross, and some letters
5–6 years	Increases running speed to 12 feet per second Gallops more smoothly; engages in true skipping Displays mature throwing and catching pattern Rides bicycle with training wheels	Uses knife to cut soft food Ties shoes Draws person with six parts Copies some numbers and simple words

## Fine-Motor Development

Fine-motor skills, too, take a giant leap forward in the preschool years. As control of the hands and fingers improves, young children put puzzles together, build with small blocks, cut and paste, and string beads. To parents, fine-motor progress is most apparent in two areas: (1) children's care of their own bodies, and (2) the drawings and paintings that fill the walls at home, child care, and preschool.

**Self-Help Skills.** As Table 7.1 shows, young children gradually become self-sufficient at dressing and feeding. But parents must be patient about these abilities: When tired and in a hurry, young children often revert to eating with their fingers. And the 3-year-old who dresses himself may end up with his shirt on inside out, his pants on backward, and his left snow boot on his right foot! The most complex self-help skill of early childhood is shoe tying, mastered around age 6. Success requires a longer attention span, memory for an intricate series of hand movements, and the dexterity to perform them. Shoe tying illustrates the close connection between motor and cognitive development, as do two other skills: drawing and writing.

**Drawing.** When given crayon and paper, even toddlers scribble in imitation of others. Gradually, marks on the page take on meaning. A variety of cognitive factors combine with fine-motor control in the development of children's artful representations (Golomb, 2004). These include the realization that pictures can serve as symbols, and improved planning and spatial understanding.

Typically, drawing progresses through the following sequence:

1. *Scribbles.* At first, children's gestures rather than the resulting scribbles contain the intended representation. For

example, one 18-month-old made her crayon hop and, as it produced a series of dots, explained, "Rabbit goes hop-hop" (Winner, 1986).

2. *First representational forms.* Around age 3, children's scribbles start to become pictures. Often children make a gesture with the crayon, notice that they have drawn a recognizable shape, and then label it (Winner, 1986). Few 3-year-olds spontaneously draw so others can tell what their picture represents. But when adults draw with children and point out the resemblances between drawings and objects, preschoolers' pictures become more comprehensible and detailed (Braswell & Callanan, 2003).

A major milestone in drawing occurs when children use lines to represent the boundaries of objects, enabling 3- and 4-year-olds to draw their first picture of a person. Fine-motor and cognitive limitations lead the preschooler to reduce the figure to the simplest form that still looks human: the universal "tadpole" image, a circular shape with lines attached, shown on the left in Figure 7.4. Four-year-olds add features, such as eyes, nose, mouth, hair, fingers, and feet.

3. *More realistic drawings.* Five- and 6-year-olds create more complex drawings, like the one on the right in Figure 7.4, containing more conventional human and animal figures, with the head and body differentiated. Older preschoolers' drawings contain perceptual distortions because they have just begun to represent depth. This free depiction of reality makes their artwork look fanciful and inventive.

### LOOK and LISTEN

Visit a preschool, child-care center, or children's museum where artwork by 3- to 5-year-olds is plentiful. Note developmental progress in drawings of human and animal figures and in the complexity of children's drawings.

**FIGURE 7.4** Examples of young children's drawings. The universal tadpolelike shape that children use to draw their first picture of a person is shown on the left. The tadpole soon becomes an anchor for details that sprout from the basic shape. By the end of the preschool years, children produce more complex, differentiated pictures like the one on the right, by a 5-year-old child. (Left: From H. Gardner, 1980, *Artful Scribbles: The Significance of Children's Drawing*, New York: Basic Books, p. 64. Copyright © 1980 by Howard Gardner. Reprinted by permission of Basic Books, a member of the Perseus Books Group, conveyed through Copyright Clearance Center. Right: © Children's Museum of the Arts New York, Permanent Collection.)

**Cultural Variations in Development of Drawing.** In cultures that have rich artistic traditions and that highly value artistic competence, children create elaborate drawings that reflect cultural conventions. Adults encourage young children by guiding them in mastering basic drawing skills, modeling ways to draw, and discussing their pictures. Peers, as well, talk about one another's drawings and copy from one another's work (Boyatzis, 2000; Braswell, 2006). All of these practices enhance drawing progress. And as the Cultural Influences box on page 226 reveals, they help explain why, from an early age, children in Asian cultures are advanced over Western children in drawing skills.

In cultures with little interest in art, even older children and adolescents produce simple forms. In the Jimi Valley, a remote region of Papua New Guinea with no indigenous pictorial art, many children do not go to school and therefore have little opportunity to develop drawing skills. When a Western researcher asked nonschooled Jimi 10- to 15-year-olds to draw a human figure for the first time, most produced nonrepresentational scribbles and shapes or simple “stick” images resembling preschoolers' tadpolelike shapes (Martlew & Connolly, 1996). These forms seem to be a universal beginning in drawing. Once children realize that lines must evoke human features, they find solutions to figure drawing that follow the general sequence described earlier.

**Early Printing.** When preschoolers first try to write, they scribble, making no distinction between writing and drawing. Around age 4, writing shows some distinctive features of print, such as separate forms arranged in a line on the page. But children often include picturelike devices—for example, a circular shape to write “sun” (Ehri & Roberts, 2006). Only gradually, between ages 4 and 6, as they learn to name alphabet letters and link them with language sounds, do children realize that writing stands for language.

Preschoolers' first attempts to print often involve their name, generally using a single letter. “How do you make a *D*?” my older son, David, asked at age 3½. When I printed a large uppercase *D*, he tried to copy. “*D* for David,” he proclaimed, quite satisfied with his backward, imperfect creation. By age 5, David printed his name clearly enough for others to read it, but, like many children, he continued to reverse some letters well into second grade. Until children start to read, they do not find it useful to distinguish between mirror-image forms, such as *b* and *d* or *p* and *q* (Bornstein & Arterberry, 1999).

## Individual Differences in Motor Skills

Wide individual differences exist in the ages at which children reach motor milestones. A tall, muscular child tends to move more quickly and to acquire certain skills earlier than a short, stocky youngster. And as in other domains, parents and teachers probably provide more encouragement to children with biologically based motor-skill advantages.

Sex differences in motor skills are evident in early childhood. Boys are ahead of girls in skills that emphasize force and power. By age 5, they can broad-jump slightly farther, run slightly faster, and throw a ball about 5 feet farther. Girls have an edge in fine-motor skills and in certain gross-motor skills that require a combination of good balance and foot movement, such as hopping and skipping (Fischman, Moore, & Steele, 1992; Haywood & Getchell, 2014). Boys' greater muscle mass and, in the case of throwing, slightly longer forearms contribute to their skill advantages. And girls' greater overall physical maturity may be partly responsible for their better balance and precision of movement.

From an early age, boys and girls are usually encouraged into different physical activities. For example, fathers are more likely to play catch with their sons than with their daughters. Sex differences in motor skills increase with age, but they remain small throughout childhood (Greendorfer, Lewko, & Rosengren, 1996). This suggests that social pressures for boys, more than girls, to be active and physically skilled exaggerate small, genetically based sex differences.

Children master the gross-motor skills of early childhood through everyday play. Aside from throwing (where direct instruction is helpful), preschoolers exposed to gymnastics, tumbling, and other formal lessons do not make faster progress. When children have access to play spaces and equipment appropriate for running, climbing, jumping, and throwing and are encouraged to use them, they respond eagerly to these challenges. Similarly, fine-motor skills can be supported through daily routines, such as dressing and pouring juice, and through richly equipped early childhood environments that include puzzles, construction sets, drawing, painting, sculpting, cutting, and pasting. And as the Cultural Influences box on page 226 shows, adults who guide and support children in acquiring drawing skills foster artistic development.

Finally, the social climate created by adults can enhance or dampen preschoolers' motor development. When parents and teachers criticize a child's performance, push specific motor skills, or promote a competitive attitude, they risk undermining children's self-confidence and, in turn, their motor progress (Berk, 2006). Adult involvement in young children's motor activities should focus on fun rather than on winning or perfecting the “correct” technique.

## Ask yourself

**CONNECT** How are experiences that best support preschoolers' gross-motor development consistent with experience-expectant brain growth of the early years? (Return to page 124 in Chapter 4 to review.)

**APPLY** Mabel and Chad want to do everything they can to support their 3-year-old daughter's motor development. What advice would you give them?

**REFLECT** Do you think that American children should be provided with systematic instruction in drawing skills beginning in early childhood, similar to the direct teaching Chinese children receive?

## Cultural Influences

### Why Are Children from Asian Cultures Advanced in Drawing Skills?

Observations of young children's drawings in Asian cultures, such as China, Japan, Korea, the Philippines, Taiwan, and Vietnam, reveal skills that are remarkably advanced over those of their Western counterparts. What explains such early artistic ability?

To answer this question, researchers examined cultural influences on children's drawings, comparing China to the United States. Artistic models offered by the culture, teaching strategies, valuing of the visual arts, and expectations for children's artistic development have a notable impact on the art that children produce.

In China's 4,000-year-old artistic tradition, adults showed children how to draw, encouraging them to master the precise steps required to depict people, butterflies, fish, birds, and other images. When taught to paint, Chinese children follow prescribed brush strokes, at first copying their teacher's model. To learn to write, they must concentrate hard on the unique details of each Chinese character—a requirement that likely enhances their drawing ability. Chinese parents and teachers believe that children can be creative only after they have acquired a foundation of artistic knowledge and technique (Golomb, 2004). To that end, China has devised a national art curriculum with standards and teaching materials extending from age 3 through secondary school.

The United States, as well, has a rich artistic tradition, but its styles and conventions are enormously diverse compared with those of Asian cultures. Children everywhere try to imitate the art around them as a way to acquire their culture's "visual language." But American children face a daunting imitative task, much like a child growing up in a context where each person speaks a different language (Cohn, 2014). Furthermore, U.S. art education emphasizes independence—finding one's own style. American teachers typically assume that copying others' drawings stifles creativity, so they discourage children

The complex drawings of these kindergartners in Shanghai, China, benefit from adult expectations that young children learn to draw well, careful teaching of artistic knowledge and technique, and the rich artistic tradition of Chinese culture.

from doing so (Copple & Bredekamp, 2009). Rather than promoting correct ways to draw, U.S. teachers emphasize imagination and self-expression.

Does the Chinese method of teaching drawing skills beginning in early childhood interfere with children's creativity? To find out, researchers followed a group of Chinese-American children of immigrant parents and a group of European-American children, all from middle-SES two-parent families, from ages 5 to 9. At two-year intervals, the children's human-figure drawings were rated for maturity and originality—inclusion of novel elements (Huntsinger et al., 2011). On each occasion, the Chinese-American children's drawings were more advanced and also more creative.

Interviews revealed that European-American parents more often provided their children with a rich variety of art materials, whereas Chinese-American parents more often enrolled their children in art lessons, rating the development of artistic competence

as more important. The Chinese-American children also spent more time as preschoolers and kindergartners in focused practice of fine-motor skills, including drawing. And the more time they spent practicing, especially when their parents taught and modeled drawing at home, the more mature their drawing skills.

At the same time, Chinese-American children's artistic creativity flourished under this systematic approach to promoting artistic maturity. Once they succeeded at drawing basic forms, they spontaneously added unusual details of their own.

In sum, even though young Chinese children are taught how to draw, their artistic products are original. Although Western children may come up with rich ideas about what to draw, until they acquire the necessary skills, they cannot implement those ideas. Cross-cultural research suggests that children benefit from adult guidance in learning to draw, just as they do in learning to talk.

## COGNITIVE DEVELOPMENT

One rainy morning, as I observed in our laboratory preschool, Leslie, the children's teacher, joined me at the back of the room. "Preschoolers' minds are such a blend of logic, fantasy, and faulty reasoning," Leslie reflected. "Every day, I'm startled by the maturity and originality of what they say and do. Yet at other times, their thinking seems limited and inflexible."

Leslie's comments sum up the puzzling contradictions of early childhood cognition. Hearing a loud thunderclap outside, 3-year-old Sammy exclaimed, "A magic man turned on the thunder!" Even after Leslie explained that thunder is caused by lightning, not by a person turning it on, Sammy persisted: "Then a magic lady did it."

In other respects, Sammy's thinking was surprisingly advanced. At snack time, he accurately counted, "One, two, three, four!" and then got four boxes of raisins, one for each child at his table. But when his snack group included more than four children, Sammy's counting broke down. And after Priti dumped out her raisins, scattering them on the table, Sammy asked, "How come you got lots, and I only got this little bit?" He didn't realize that he had just as many raisins; his were simply all bunched up in a tiny red box. While Priti washed her hands after snack time, Sammy stuffed her remaining raisins back in the box and placed it in her cubby. When Priti returned and looked for her raisins, Sammy insisted, "You know where they are!" He failed to consider that Priti, who hadn't seen him move the raisins, would expect them to be where she had left them.

To understand Sammy's reasoning, we turn first to Piaget's and Vygotsky's theories along with evidence highlighting the strengths and limitations of each. Then we take up additional research on young children's cognition inspired by the information-processing perspective, address factors that contribute to individual differences in mental development, and conclude with the dramatic expansion of language in early childhood.

### Piaget's Theory: The Preoperational Stage

**7.5** Describe advances in mental representation, and limitations of thinking, during the preoperational stage.

**7.6** What does follow-up research imply about the accuracy of Piaget's preoperational stage?

**7.7** What educational principles can be derived from Piaget's theory?

As children move from the sensorimotor to the **preoperational stage**, which spans the years 2 to 7, the most obvious change is an extraordinary increase in representational, or symbolic, activity. Infants and toddlers' mental representations are impressive, but in early childhood, these capacities blossom.

## Advances in Mental Representation

Piaget acknowledged that language is our most flexible means of mental representation. By detaching thought from action, it permits far more efficient thinking than was possible earlier. When we think in words, we overcome the limits of our momentary experiences. We can deal with past, present, and future at once and combine concepts in unique ways, as when we imagine a hungry caterpillar eating bananas or monsters flying through the forest at night.

But Piaget did not regard language as the primary ingredient in childhood cognitive change. Instead, he believed that sensorimotor activity leads to internal images of experience, which children then label with words (Piaget, 1936/1952). In support of Piaget's view, recall from Chapter 5 that children's first words have a strong sensorimotor basis. And toddlers acquire an impressive range of categories long before they use words to label them (see page 165). But as we will see, Piaget underestimated the power of language to spur children's cognition.

## Make-Believe Play

Make-believe play is another excellent example of the development of representation in early childhood. Piaget believed that through pretending, young children practice and strengthen newly acquired representational schemes. Drawing on his ideas, several investigators have traced changes in make-believe play during the preschool years.

**Development of Make-Believe.** One day, Sammy's 20-month-old brother, Dwayne, visited the classroom. Dwayne wandered around, picked up a toy telephone receiver, said, "Hi, Mommy," and then dropped it. Next, he found a cup, pretended to drink, and toddled off again. Meanwhile, Sammy joined Vance and Priti in the block area for a space shuttle launch.

© ELLEN B. SENSI

Make-believe play increases in sophistication during the preschool years. Children pretend with less realistic toys and increasingly coordinate make-believe roles, such as school bus driver and passengers.

“That can be our control tower,” Sammy suggested, pointing to a corner by a bookshelf. “Countdown!” he announced, speaking into his “walkie-talkie”—a small wooden block. “Five, six, two, four, one, blastoff!” Priti made a doll push a pretend button, and the rocket was off!

Comparing Dwayne’s pretend play with Sammy’s, we see three important changes that reflect the preschool child’s growing symbolic mastery:

- *Play detaches from the real-life conditions associated with it.* In early pretending, toddlers use only realistic objects—a toy telephone to talk into or a cup to drink from. Their earliest pretend acts usually imitate adults’ actions and are not yet flexible. Children younger than age 2, for example, will pretend to drink from a cup but refuse to pretend a cup is a hat (Rakoczy, Tomasello, & Striano, 2005). They have trouble using an object (cup) that already has an obvious use as a symbol of another object (hat).  
After age 2, children pretend with less realistic toys (a block for a telephone receiver). Gradually, they can imagine objects and events without any support from the real world, as Sammy’s imaginary control tower illustrates (Striano, Tomasello, & Rochat, 2001). And by age 3, they flexibly understand that an object (a yellow stick) may take on one fictional identity (a toothbrush) in one fictional game and another fictional identity (a carrot) in a different pretend game (Wyman, Rakoczy, & Tomasello, 2009).
- *Play becomes less self-centered.* At first, make-believe is directed toward the self—for example, Dwayne pretends to feed only himself. Soon, children direct pretend actions toward other objects, as when a child feeds a doll. Early in the third year, they become detached participants, making a doll feed itself or pushing a button to launch a rocket (McCune, 1993). Increasingly, preschoolers realize that agents and recipients of pretend actions can be independent of themselves.
- *Play includes more complex combinations of schemes.* Dwayne can pretend to drink from a cup, but he does not yet combine pouring and drinking. Later, children combine schemes with those of peers in **sociodramatic play**, the make-believe with others that is under way by the end of the second year and increases rapidly in complexity during early childhood (Kavanaugh, 2006). Already, Sammy and his classmates can create and coordinate several roles in an elaborate plot. By the end of early childhood, children have a sophisticated understanding of role relationships and story lines.

## LOOK and LISTEN

Observe the make-believe play of several preschoolers at a family gathering, a preschool or child-care center, or in another community setting. Describe pretend acts that illustrate important developmental changes.

In sociodramatic play, children display awareness that make-believe is a representational activity—an understanding that strengthens over early childhood (Rakoczy, Tomasello, & Striano, 2004; Sobel, 2006). Listen closely to a group of preschoolers as they assign roles and negotiate make-believe plans: “You *pretend to be* the astronaut, I’ll *act like* I’m operating the control tower!” In communicating about pretend, children think about their own and others’ fanciful representations—evidence that they have begun to reason about people’s mental activities, a topic we will return to later in this chapter.

**Benefits of Make-Believe.** Today, many researchers regard Piaget’s view of make-believe as mere practice of representational schemes as too limited. In their view, play not only reflects but also contributes to children’s cognitive and social skills.

Research reveals that preschoolers who devote more time to sociodramatic play are rated by observers as more socially competent a year later (Lindsey & Colwell, 2013). And make-believe predicts a wide variety of cognitive capacities, including executive function, memory, logical reasoning, language and literacy (including story comprehension and storytelling skills), imagination, creativity, and the ability to reflect on one’s own thinking, regulate emotions, and take another’s perspective (Berk & Meyers, 2013; Buchsbaum et al., 2012; Carlson & White, 2013; Mottweiler & Taylor, 2014; Nicolopoulou & Ilgaz, 2013; Roskos & Christie, 2013).

Critics, however, point out that the evidence just summarized is largely correlational, with too many studies failing to control all factors that might alternatively explain their findings (Lillard et al., 2013). In response, play investigators note that decades of research are consistent with a positive role for make-believe play in development and that new, carefully conducted research strengthens that conclusion (Berk, 2015; Carlson, White, & Davis-Unger, 2015). Furthermore, make-believe is difficult to study experimentally, by training children to engage in it. Besides alterations of reality, true make-believe *play* involves other qualities, including intrinsic motivation (doing it for fun, not to please an adult), positive emotion, and child control (Bergen, 2013).

Finally, much make-believe takes place when adults are not around to observe it! For example, an estimated 25 to 45 percent of preschoolers and young school-age children spend much time creating imaginary companions—special fantasized friends endowed with humanlike qualities. Yet more than one-fourth of parents are unaware of their child’s invisible friend (Taylor et al., 2004). Children with imaginary companions display more complex and imaginative make-believe play; more often describe others in terms of their internal states, including desires, thoughts, and emotions; and are more sociable with peers (Bouldin, 2006; Davis, Meins, & Fernyhough, 2014; Gleason, 2013).

## Symbol–Real-World Relations

To make believe and draw—and to understand other forms of representation, such as photographs, models, and maps—

preschoolers must realize that each symbol corresponds to something specific in everyday life. In Chapter 5, we saw that by the middle of the second year, children grasp the symbolic function of realistic-looking pictures, and around age 2½, of TV and video. When do children comprehend other challenging symbols—for example, three-dimensional models of real-world spaces?

In one study, 2½- and 3-year-olds watched an adult hide a small toy (Little Snoopy) in a scale model of a room and then were asked to retrieve it. Next, they had to find a larger toy (Big Snoopy) hidden in the room that the model represented. Not until age 3 could most children use the model as a guide to finding Big Snoopy in the real room (DeLoache, 1987). The 2½-year-olds did not realize that the model could be both *a toy room* and *a symbol of another room*. They had trouble with **dual representation**—viewing a symbolic object as both an object in its own right and a symbol. In support of this interpretation, when researchers made the model room less prominent as an object, by placing it behind a window and preventing children from touching it, more 2½-year-olds succeeded at the search task (DeLoache, 2002). Recall, also, that in make-believe play, 1½- to 2-year-olds cannot use an object that has an obvious use (cup) to stand for another object (hat).

How do children grasp the dual representation of symbolic objects? When adults point out similarities between models and real-world spaces, 2½-year-olds perform better on the find-Snoopy task (Peralta de Mendoza & Salsa, 2003). Also, insight into one type of symbol–real-world relation helps preschoolers master others. For example, children regard realistic-looking pictures as symbols early because a picture’s primary purpose is to stand for something; it is not an interesting object in its own right (Simcock & DeLoache, 2006). And 3-year-olds who can use a model of a room to locate Big Snoopy readily transfer their understanding to a simple map (Marzolf & DeLoache, 1994).

In sum, experiences with diverse symbols—picture books, photographs, drawings, make-believe, and maps—help preschoolers appreciate that one object can stand for another. With age, children come to understand a wide range of symbols that have little physical similarity to what they represent. As a result, doors open to vast realms of knowledge.

## Limitations of Preoperational Thought

Aside from gains in representation, Piaget described preschoolers in terms of what they *cannot* understand. As the term *preoperational* suggests, he compared them to older, more competent children who have reached the concrete operational stage. According to Piaget, young children are not capable of *operations*—mental representations of actions that obey logical rules. Rather, their thinking is rigid, limited to one aspect of a situation at a time, and strongly influenced by the way things appear at the moment.

**Egocentrism.** For Piaget, the most fundamental deficiency of preoperational thinking is **egocentrism**—failure to distinguish others’ symbolic viewpoints from one’s own. He believed that

**FIGURE 7.5 Piaget’s three-mountains problem.** Each mountain is distinguished by its color and by its summit. One has a red cross, another a small house, and the third a snow-capped peak. Children at the preoperational stage respond egocentrically. They cannot select a picture that shows the mountains from the doll’s perspective. Instead, they simply choose the photo that reflects their own vantage point.

when children first mentally represent the world, they tend to focus on their own viewpoint and simply assume that others perceive, think, and feel the same way they do.

Piaget’s most convincing demonstration of egocentrism involves his *three-mountains problem*, described in Figure 7.5. He also regarded egocentrism as responsible for preoperational children’s *animistic thinking*—the belief that inanimate objects have lifelike qualities, such as thoughts, wishes, feelings, and intentions (Piaget, 1926/1930). Recall Sammy’s insistence that someone must have turned on the thunder. According to Piaget, because young children egocentrically assign human purposes to physical events, magical thinking is common during the preschool years.

Piaget argued that preschoolers’ egocentric bias prevents them from *accommodating*, or reflecting on and revising their faulty reasoning in response to their physical and social worlds. To understand this shortcoming, let’s consider some additional tasks that Piaget gave to children.

**Inability to Conserve.** Piaget’s famous conservation tasks reveal a variety of deficiencies of preoperational thinking. **Conservation** refers to the idea that certain physical characteristics of objects remain the same, even when their outward appearance changes. At snack time, Priti and Sammy had identical boxes of raisins, but when Priti spread her raisins out on the table, Sammy was convinced that she had more.

In another conservation task involving liquid, the child is shown two identical tall glasses of water and asked if they contain equal amounts. Once the child agrees, the water in one glass is poured into a short, wide container, changing its appearance

**FIGURE 7.6** Some Piagetian conservation tasks. Children at the preoperational stage cannot yet conserve. These tasks are mastered gradually over the concrete operational stage. Children in Western nations typically acquire conservation of number, mass, and liquid sometime between 6 and 7 years and conservation of weight between 8 and 10 years.

but not its amount. Then the child is asked whether the amount of water has changed. Preoperational children think the quantity has changed. They explain, “There is less now because the water is way down here” (that is, its level is so low) or, “There is more now because it is all spread out.” Figure 7.6 illustrates other conservation tasks that you can try with children.

The inability to conserve highlights several related aspects of preoperational children’s thinking. First, their understanding is *centered*, or characterized by **centration**. They focus on one aspect of a situation, neglecting other important features. In conservation of liquid, the child *centers* on the height of the water, failing to realize that changes in width compensate for changes in height. Second, children are easily distracted by the *perceptual appearance* of objects. Third, children treat the initial and final states of the water as unrelated events, ignoring the *dynamic transformation* (pouring of water) between them.

The most important illogical feature of preoperational thought is its **irreversibility**—an inability to mentally go through a series of steps in a problem and then reverse direction, returning to the starting point. *Reversibility* is part of every logical operation. After Priti spills her raisins, Sammy cannot reverse by thinking, “I know that Priti doesn’t have more raisins than I do. If we put them back in that little box, her raisins and my raisins would look just the same.”

**Lack of Hierarchical Classification.** Preoperational children have difficulty with **hierarchical classification**—the

organization of objects into classes and subclasses on the basis of similarities and differences. Piaget’s famous *class inclusion problem*, illustrated in Figure 7.7, demonstrates this limitation. Preoperational children center on the overriding feature, red. They do not think reversibly by moving from the whole class (flowers) to the parts (red and blue) and back again.

**FIGURE 7.7** A Piagetian class inclusion problem. Children are shown 16 flowers, 4 of which are blue and 12 of which are red. Asked, “Are there more red flowers or flowers?” the preoperational child responds, “More red flowers,” failing to realize that both red and blue flowers are included in the category “flowers.”

## Follow-Up Research on Preoperational Thought

Over the past three decades, researchers have challenged Piaget's view of preschoolers as cognitively deficient. Because many Piagetian problems contain unfamiliar elements or too many pieces of information for young children to handle at once, preschoolers' responses do not reflect their true abilities. Piaget also missed many naturally occurring instances of effective reasoning by preschoolers.

**Egocentric, Animistic, and Magical Thinking.** Do young children really believe that a person standing elsewhere in a room sees exactly what they see? When researchers use simplified tasks with familiar objects, 3-year-olds show clear awareness of others' vantage points, such as recognizing how something appears to another person who is looking at it through a color filter (Moll & Meltzoff, 2011).

Nonegocentric responses also appear in young children's conversations. For example, 4-year-olds use shorter, simpler expressions when talking to 2-year-olds than to age-mates or adults (Gelman & Shatz, 1978). And in describing objects, preschoolers do not use such words as "big" and "little" in a rigid, egocentric fashion. Instead, they *adjust* their descriptions to allow for context. By age 3, they judge a 2-inch shoe as little when seen by itself (because it is much smaller than most shoes) but as big for a tiny 5-inch-tall doll (Ebeling & Gelman, 1994).

In Chapter 5, we saw that toddlers have already begun to infer others' intentions (see page 155). And in his later writings, Piaget (1945/1951) did describe preschoolers' egocentrism as a *tendency* rather than an inability. As we revisit the topic of perspective taking, we will see that it develops gradually throughout childhood and adolescence.

Piaget also overestimated preschoolers' animistic beliefs. Even infants have begun to distinguish animate from inanimate, as indicated by their developing categorical distinctions between living and nonliving things (see page 164). By age 2½, children give psychological explanations ("he likes to" or "she wants to") for people and occasionally for other animals, but rarely for objects (Hickling & Wellman, 2001). In addition, preschoolers rarely attribute biological properties (like eating and growing) to robots, indicating that they are well aware that even a self-moving object with lifelike features is not alive. But unlike adults, they often say that robots have perceptual and psychological capacities—for example, seeing, thinking, and remembering (Jipson & Gelman, 2007; Subrahmanyam, Gelman, & Lafosse, 2002). These responses result from incomplete knowledge about certain objects, and they decline with age.

Similarly, preschoolers think that magic accounts for events they otherwise cannot explain, as in Sammy's magical explanation of thunder in the opening to this chapter. But their notions of magic are flexible and appropriate. For example, 3- and 4-year-olds are more likely to say that a magical process—wishing—caused an event (an object to appear in a box) when a person made the wish before the event occurred, the event is consistent

© TATSUYUKI TAYAMA/FUJIFOTOS/THE IMAGE WORKS

Preschoolers distinguish between animate and inanimate and realize, for example, that a robot with lifelike features cannot eat or grow. But because of incomplete knowledge, they often claim that robots have perceptual and psychological capacities, such as seeing, thinking, and remembering.

with the wish (the wished-for object rather than another object appeared in the box), and no alternative causes were apparent (Woolley, Browne, & Boerger, 2006). These features of causality are the same ones preschoolers rely on in ordinary situations.

Between ages 4 and 8, as children gain familiarity with physical events and principles, their magical beliefs decline. They figure out who is behind Santa Claus and the Tooth Fairy, realize that magicians' feats are due to trickery, and say that characters and events in fantastical stories aren't real (Woolley & Cornelius, 2013; Woolley & Cox, 2007). Still, because children entertain the possibility that something they imagine might materialize, they may react with anxiety to scary stories, TV shows, and nightmares.

**Logical Thought.** Many studies show that when preschoolers are given tasks that are simplified and relevant to their everyday lives, they do not display the illogical characteristics that Piaget saw in the preoperational stage. For example, when a conservation-of-number task is scaled down to include only three items instead of six or seven, 3-year-olds perform well (Gelman, 1972). And when asked carefully worded questions about what happens to a substance (such as sugar) after it is dissolved in water, most 3- to 5-year-olds know that the substance is conserved—that it continues to exist, can be tasted, and makes the liquid heavier, even though it is invisible in the water (Au, Sidle, & Rollins, 1993; Rosen & Rozin, 1993).

### LOOK and LISTEN

Try the conservation of number and mass tasks in Figure 7.6 with a 3- or 4-year-old. Next, simplify conservation of number by reducing the number of pennies, and relate conservation of mass to the child's experience by pretending the clay is baking dough and transforming it into cupcakes. Did the child perform more competently?

Preschoolers' ability to reason about transformations is evident on other problems. They can engage in impressive *reasoning by analogy* about physical changes. Presented with the picture-matching problem "Play dough is to cut-up play dough as apple is to . . . ?," even 3-year-olds choose the correct answer (a cut-up apple) from a set of alternatives, several of which (a bitten apple, a cut-up loaf of bread) share physical features with the right choice (Goswami, 1996). These findings indicate that in familiar contexts, preschoolers can overcome appearances and think logically about cause and effect.

Finally, even without detailed biological or mechanical knowledge, preschoolers understand that the insides of animals are responsible for certain cause-effect sequences (such as willing oneself to move) that are impossible for nonliving things, such as machines (Gelman, 2003). They seem to use illogical reasoning only when grappling with unfamiliar topics, too much information, or contradictory facts that they cannot reconcile.

**Categorization.** Despite their difficulty with Piagetian class inclusion tasks, preschoolers organize their everyday knowledge into nested categories at an early age. By the beginning of early childhood, children's categories include objects that go together because of their common function, behavior, or natural kind (animate versus inanimate), despite varying widely in perceptual features.

Indeed, 2- to 5-year-olds readily draw appropriate inferences about nonobservable characteristics shared by category members

(Gopnik & Nazzi, 2003). For example, after being told that a bird has warm blood and that a stegosaurus (dinosaur) has cold blood, preschoolers infer that a pterodactyl (labeled a dinosaur) has cold blood, even though it closely resembles a bird.

Nevertheless, when most instances of a category have a certain perceptual property (such as long ears), preschoolers readily categorize on the basis of perceptual features. This indicates that they flexibly use different types of information to classify, depending on the situation (Rakison & Lawson, 2013). And past experiences influence the information they decide to use. Native-American 5-year-olds growing up on the Menominee Reservation in northern Wisconsin often use relations in the natural world to categorize animals—for example, grouping together wolves and eagles because of their shared forest habitat (Ross et al., 2003). European-American children, in contrast, mostly rely on the animals' common features.

During the second and third years, and perhaps earlier, children's categories differentiate. They form many *basic-level categories*—ones that are at an intermediate level of generality, such as "chairs," "tables," and "beds." By the third year, children easily move back and forth between basic-level categories and *general categories*, such as "furniture." And they break down basic-level categories into *subcategories*, such as "rocking chairs" and "desk chairs."

Preschoolers' rapidly expanding vocabularies and general knowledge support their impressive skill at categorizing, and they benefit greatly from conversations with adults, who frequently label and explain categories to them. When adults use the word *bird* for hummingbirds, turkeys, and swans, they signal to children that something other than physical similarity binds these instances together (Gelman & Kalish, 2006). Children also ask many questions about their world, the majority of which are information-seeking: "What's that? What does it do?" (Chouinard, 2007). Usually, parents give informative answers that advance conceptual understanding. Picture-book reading is an especially rich context for category learning. In conversing about books, parents provide information that guides children's inferences about the structure of categories: "Penguins live at the South Pole, swim, catch fish, and have thick layers of fat and feathers that help them stay warm."

In sum, although preschoolers' category systems are less complex than those of older children and adults, they already have the capacity to classify hierarchically and on the basis of nonobvious properties. And they use logical, causal reasoning to identify the interrelated features that form the basis of a category and to classify new members.

## Evaluation of the Preoperational Stage

Table 7.2 provides an overview of the cognitive attainments of early childhood. Compare them with Piaget's description of the preoperational child on pages 229–230. The evidence as a whole indicates that Piaget was partly wrong and partly right about young children's cognitive capacities. When given simplified tasks based on familiar experiences, preschoolers show the

© LAURA DWIGHT PHOTOGRAPHY

These 4-year-olds understand that a category ("dinosaurs") can be based on underlying characteristics ("cold-blooded"), not just on perceptual features such as upright posture and scaly skin.

**TABLE 7.2**  
**Some Cognitive Attainments of Early Childhood**

APPROXIMATE AGE	COGNITIVE ATTAINMENTS
2–4 years  <small>© ELLEN B. SENISI</small>	Shows a dramatic increase in representational activity, as reflected in the development of language, make-believe play, understanding of dual representation, and categorization Takes the perspective of others in simplified, familiar situations and in everyday, face-to-face communication Distinguishes animate beings from inanimate objects; prefers natural over supernatural explanations for events Grasps conservation, notices transformations, reverses thinking, and understands many cause-and-effect relationships in simplified, familiar situations Categorizes objects on the basis of common function, behavior, and natural kind as well as perceptual features, depending on context; uses inner causal features to categorize objects varying widely in external appearance Sorts familiar objects into hierarchically organized categories
4–7 years  <small>RYAN MCVAY/PHOTODISC/GETTY IMAGES</small>	Becomes increasingly aware that make-believe and other thought processes are representational activities Replaces beliefs in magical creatures and events with plausible explanations Passes Piaget's conservation of number, mass, and liquid problems

beginnings of logical thinking, which suggest that they attain logical operations gradually.

Evidence that preschoolers can be trained to perform well on Piagetian problems also supports the idea that operational thought is not absent at one point in time and present at another (Ping & Goldin-Meadow, 2008). Over time, children rely on increasingly effective mental (as opposed to perceptual) approaches to solving problems. For example, children who cannot use counting to compare two sets of items do not conserve number (Rouselle, Palmers, & Noël, 2004). Once preschoolers can count, they apply this skill to conservation-of-number tasks involving just a few items. As counting improves, they extend the strategy to problems with more items. By age 6, they understand that number remains the same after a transformation as long as nothing is added or taken away (Halford & Andrews, 2011). Consequently, they no longer need to count to verify their answer.

The gradual development of logical operations poses yet another challenge to Piaget's assumption of abrupt change toward logical reasoning around age 6 or 7. Does a preoperational stage really exist? Some no longer think so. Recall from Chapter 5 that according to the information-processing perspective, children work out their understanding of each type of task separately, and their thought processes are basically the same at all ages—just present to a greater or lesser extent.

Other experts think the stage concept is still valid, with modifications. For example, some *neo-Piagetian theorists* combine Piaget's stage approach with the information-processing emphasis on task-specific change (Case, 1998; Halford & Andrews, 2011). They believe that Piaget's strict stage definition must be

transformed into a less tightly knit concept, one in which a related set of competencies develops over an extended period, depending on brain development and specific experiences. These investigators point to evidence that as long as the complexity of tasks and children's exposure to them are carefully controlled, children approach those tasks in similar, stage-consistent ways (Andrews & Halford, 2002; Case & Okamoto, 1996). For example, in drawing pictures, preschoolers depict objects separately, ignoring their spatial arrangement. In understanding stories, they grasp a single story line but have trouble with a main plot plus one or more subplots.

This flexible stage notion recognizes the unique qualities of early childhood thinking. At the same time, it provides a better account of why, as Leslie put it, "Preschoolers' minds are such a blend of logic, fantasy, and faulty reasoning."

## Piaget and Education

Three educational principles derived from Piaget's theory continue to influence teacher training and classroom practices, especially during early childhood:

- *Discovery learning.* In a Piagetian classroom, children are encouraged to discover for themselves through spontaneous interaction with the environment. Instead of presenting ready-made knowledge verbally, teachers provide a rich variety of activities designed to promote exploration, including art, puzzles, table games, dress-up clothing, building blocks, books, measuring tools, natural science tasks, and musical instruments.

- *Sensitivity to children’s readiness to learn.* In a Piagetian classroom, teachers introduce activities that build on children’s current thinking, challenging their incorrect ways of viewing the world. But they do not try to speed up development by imposing new skills before children indicate interest or readiness.
- *Acceptance of individual differences.* Piaget’s theory assumes that all children go through the same sequence of development, but at different rates. Therefore, teachers must plan activities for individual children and small groups, not just for the whole class. In addition, teachers evaluate educational progress in relation to each child’s previous development, rather than on the basis of attaining normative standards.

Like his stages, educational applications of Piaget’s theory have met with criticism, especially his insistence that young children learn primarily through acting on the environment (Brainerd, 2003). In the next section, we will see that they also rely on language-based routes to knowledge.

## Ask yourself

**CONNECT** Select two of the following features of preoperational thought: egocentrism, a focus on perceptual appearances, difficulty reasoning about transformations, and lack of hierarchical classification. Present evidence indicating that preschoolers are more capable thinkers than Piaget assumed.

**APPLY** Three-year-old Will understands that his tricycle isn’t alive and can’t feel or move on its own. But at the beach, while watching the sun dip below the horizon, Will exclaimed, “The sun is tired. It’s going to sleep!” What explains this apparent contradiction in Will’s reasoning?

**REFLECT** Did you have an imaginary companion as a young child? If so, what was your companion like, and why did you create it?

## Vygotsky’s Sociocultural Theory

**7.8** Describe Vygotsky’s perspective on the social origins and significance of children’s private speech.

**7.9** Describe applications of Vygotsky’s theory to education, and evaluate his major ideas.

Piaget’s de-emphasis on language as a source of cognitive development brought on yet another challenge, this time from Vygotsky’s sociocultural theory, which stresses the social context of cognitive development. During early childhood, rapid expansion of language broadens preschoolers’ participation in social dialogues with more knowledgeable individuals, who encourage them to master culturally important tasks. Soon children start to communicate with themselves in much the same way they

converse with others. This greatly enhances their thinking and ability to control their own behavior. Let’s see how this happens.

## Private Speech

Watch preschoolers as they play and explore the environment, and you will see that they frequently talk out loud to themselves. For example, as Sammy worked a puzzle, he said, “Where’s the red piece? Now, a blue one. No, it doesn’t fit. Try it here.”

Piaget (1923/1926) called these utterances *egocentric speech*, reflecting his belief that young children have difficulty taking the perspectives of others. Their talk, he said, is often “talk for self” in which they express thoughts in whatever form they happen to occur, regardless of whether a listener can understand. As egocentrism declines, so does this poorly adapted speech.

Vygotsky (1934/1987) disagreed with Piaget’s conclusions. He maintained that language helps children think about their mental activities and behavior and select courses of action, thereby serving as the foundation for all higher cognitive processes, including controlled attention, deliberate memorization and recall, categorization, planning, problem solving, and self-reflection. In Vygotsky’s view, children speak to themselves for self-guidance. As they get older and find tasks easier, their self-directed speech is internalized as silent, *inner speech*—the internal verbal dialogues we carry on while thinking and acting in everyday situations.

Because almost all studies support Vygotsky’s perspective, children’s self-directed speech is now called **private speech** instead of egocentric speech. Research shows that children use

© LAURA DWIGHT PHOTOGRAPHY

A 4-year-old talks to herself as she draws. Research supports Vygotsky’s theory that children use private speech to guide their thinking and behavior.

more of it when tasks are appropriately challenging (neither too easy nor too hard), after they make errors, or when they are confused about how to proceed. With age, as Vygotsky predicted, private speech goes underground, changing into whispers and silent lip movements. Furthermore, children who freely use private speech during a challenging activity are more attentive and involved and show better task performance than their less talkative agemates (Benigno et al., 2011; Lidstone, Meins, & Fernyhough, 2010; Winsler, 2009).

## Social Origins of Early Childhood Cognition

Where does private speech come from? Recall from Chapter 5 that Vygotsky believed that children’s learning takes place within the *zone of proximal development*—a range of tasks too difficult for the child to do alone but possible with the help of others. Consider the joint activity of Sammy and his mother as she helps him put together a difficult puzzle:

*Sammy:* I can’t get this one in. [*Tries to insert a piece in the wrong place.*]

*Mother:* Which piece might go down here? [*Points to the bottom of the puzzle.*]

*Sammy:* His shoes. [*Looks for a piece resembling the clown’s shoes but tries the wrong one.*]

*Mother:* Well, what piece looks like this shape? [*Points again to the bottom of the puzzle.*]

*Sammy:* The brown one. [*Tries it, and it fits; then attempts another piece and looks at his mother.*]

*Mother:* Try turning it just a little. [*Gestures to show him.*]

*Sammy:* There! [*Puts in several more pieces while his mother watches.*]

Sammy’s mother keeps the puzzle within his zone of proximal development, at a manageable level of difficulty. To do so, she engages in **scaffolding**—adjusting the support offered during a teaching session to fit the child’s current level of performance. When the child has little notion of how to proceed, the adult uses direct instruction, breaking the task into manageable units, suggesting strategies, and offering rationales for using them. As the child’s competence increases, effective scaffolders gradually and sensitively withdraw support, turning over responsibility to the child. Then children take the language of these dialogues, make it part of their private speech, and use this speech to organize their independent efforts.

Although preschoolers freely use private speech when alone or with others, they use more in the presence of others (McGonigle-Chalmers, Slater, & Smith, 2014). This suggests that some private speech retains a social purpose, perhaps as an indirect appeal for renewed scaffolding should the child need additional help. In several studies, children whose parents were effective scaffolders engaged in higher rates of private speech, were more likely to succeed when attempting challenging tasks on their own, and were advanced in overall cognitive development (Berk & Spuhl, 1995; Conner & Cross, 2003; Mulvaney et al., 2006).

Nevertheless, effective scaffolding can take different forms in different cultures. In an investigation of Hmong families who had emigrated from Southeast Asia to the United States, once again, parental cognitive support was associated with children’s advanced reasoning skills. But unlike European-American parents, who emphasize independence by encouraging their children to think of ways to approach a task, Hmong parents—who highly value interdependence and child obedience—frequently tell their children what to do (for example, “Put this piece here, then this piece on top of it”) (Stright, Herr, & Neitzel, 2009). Among European-American children, such directive scaffolding is associated with kindergartners’ lack of self-control and behavior problems (Neitzel & Stright, 2003). Among the Hmong children, it predicted capacity to follow rules, be organized, and finish assignments.

## Vygotsky and Early Childhood Education

Both Piagetian and Vygotskian classrooms emphasize active participation and acceptance of individual differences. But a Vygotskian classroom goes beyond independent discovery to promote *assisted discovery*. Teachers guide children’s learning, tailoring their interventions to each child’s zone of proximal development. Assisted discovery is aided by *peer collaboration*, as children of varying abilities work in groups, teaching and helping one another.

© LAURA DWIGHT PHOTOGRAPHY

In this Vygotsky-inspired classroom, preschoolers benefit from peer collaboration as they jointly create an elaborate block structure.

Vygotsky (1933/1978) saw make-believe play as the ideal social context for fostering cognitive development in early childhood. As children create imaginary situations, they learn to follow internal ideas and social rules rather than impulses. For example, a child pretending to go to sleep follows the rules of bedtime behavior. A child imagining himself as a father and a doll as a child conforms to the rules of parental behavior (Meyers & Berk, 2014). According to Vygotsky, make-believe play is a unique, broadly influential zone of proximal development in which children try out a wide variety of challenging activities and acquire many new competencies.

Turn back to page 228 to review evidence on the contributions of make-believe play to cognitive and social development. Pretending is also rich in private speech—a finding that supports its role in helping children bring action under the control of thought (Krafft & Berk, 1998). Preschoolers who spend more time engaged in sociodramatic play are better at inhibiting impulses, regulating emotion, and taking personal responsibility for following classroom rules (Elias & Berk, 2002; Kelly & Hammond, 2011; Lemche et al., 2003). These findings support the role of make-believe in children’s increasing self-control.

## Evaluation of Vygotsky’s Theory

In granting social experience a fundamental role in cognitive development, Vygotsky’s theory underscores the power of teaching and helps us understand the wide cultural variation in children’s cognitive skills. Nevertheless, his theory has not gone unchallenged. In some cultures, verbal dialogues are not the only—or even the most important—means through which children learn. When Western parents scaffold their young children’s mastery of challenging tasks, their verbal communication resembles the teaching that occurs in school, where their children will spend years preparing for adult life. In cultures that place less emphasis on schooling and literacy, parents often expect children to take greater responsibility for acquiring new skills through keen observation and participation in community activities (Rogoff, Correa-Chavez, & Silva, 2011). See the Cultural Influences box on the following page for research illustrating this difference.

To account for children’s diverse ways of learning through involvement with others, Barbara Rogoff (2003) suggests the term **guided participation**, a broader concept than scaffolding. It refers to shared endeavors between more expert and less expert participants, without specifying the precise features of communication. Consequently, it allows for variations across situations and cultures.

Finally, Vygotsky’s theory says little about how basic motor, perceptual, attention, memory, and problem-solving skills, discussed in Chapters 4 and 5, contribute to socially transmitted higher cognitive processes. For example, his theory does not address how these elementary capacities spark changes in children’s social experiences, from which more advanced cognition springs (Daniels, 2011; Miller, 2009). Piaget paid far more attention than Vygotsky to the development of basic cognitive pro-

cesses. It is intriguing to speculate about the broader theory that might exist today had Piaget and Vygotsky—the two twentieth-century giants of cognitive development—had a chance to meet and weave together their extraordinary accomplishments.

## Ask yourself

**CONNECT** Explain how Piaget’s and Vygotsky’s theories complement each other. How would classroom practices inspired by these theories be similar? How would they differ?

**APPLY** Tanisha sees her 5-year-old son, Toby, talking aloud to himself as he plays. She wonders whether she should discourage this behavior. Use Vygotsky’s theory to explain to Tanisha why Toby talks to himself.

**REFLECT** When do you use private speech? Does it serve a self-guiding function for you, as it does for children? Explain.

## Information Processing

**7.10** How do executive function and memory change during early childhood?

**7.11** Describe the young child’s theory of mind.

**7.12** Summarize children’s literacy and mathematical knowledge during early childhood.

Return to the model of information processing discussed on page 160 in Chapter 5. Recall that information processing focuses on cognitive operations and mental strategies that children use to transform stimuli flowing into their mental systems. As we have already seen, early childhood is a period of dramatic strides in mental representation. And the various components of *executive function* that help us succeed in cognitively challenging situations—inhibiting impulses and distracting stimuli, flexibly shifting attention depending on task demands, coordinating information in working memory, and planning—show impressive gains (Carlson, Zelazo, & Faja, 2013). Preschoolers also become more aware of their own mental life and begin to acquire academically relevant knowledge important for school success.

## Executive Function

As parents and teachers know, preschoolers—compared with school-age children—spend shorter times involved in tasks and are more easily distracted. Control of attention improves substantially during early childhood, as studies of inhibition and flexible shifting reveal. As we will see, expansion of working memory supports these attainments. The components of executive function are closely interrelated in early childhood, and they contribute vitally to academic social skills from early childhood on (Shaul & Schwartz, 2014).

## Cultural Influences

### Children in Village and Tribal Cultures Observe and Participate in Adult Work

In Western societies, the role of equipping children with the skills they need to become competent workers is assigned to school. In early childhood, middle-SES parents' interactions with children emphasize child-focused activities designed to prepare them to succeed academically—especially adult-child conversations and play that enhance language, literacy, and other school-related knowledge. In village and tribal cultures, children receive little or no schooling, spend their days in contact with or participating in adult work, and start to assume mature responsibilities in early childhood (Gaskins, 2014). Consequently, parents have little need to rely on conversation and play to teach children.

A study comparing 2- and 3-year-olds' daily lives in four cultures—two U.S. middle-SES suburbs, the Efe hunters and gatherers of the Republic of Congo, and a Mayan agricultural town in Guatemala—documented these differences (Morelli, Rogoff, & Angelillo, 2003). In the U.S. communities, young children had little access to adult work and spent much time conversing and playing with adults. The Efe and Mayan children spent their days close to—and frequently observing—adult work, which often took place in or near the Efe campsite or the Mayan family home.

An ethnography of a remote Mayan village in Yucatán, Mexico, shows that when young children are legitimate onlookers and participants in a daily life structured around adult work, their competencies differ from those of Western preschoolers (Gaskins, 1999; Gaskins,

Haight, & Lancy, 2007). Yucatec Mayan adults are subsistence farmers. Men tend cornfields, aided by sons age 8 and older. Women prepare meals, wash clothes, and care for the livestock and garden, assisted by daughters and by sons too young to work in the fields. Children join in these activities from the second year on. When not participating, they are expected to be self-sufficient.

Young children make many nonwork decisions for themselves—how much to sleep and eat, what to wear, and even when to start school. As a result, Yucatec Mayan preschoolers are highly competent at self-care. In contrast, their make-believe play is limited; when it occurs, they usually imitate adult work. Otherwise, they watch others—for hours each day.

Yucatec Mayan parents rarely converse or play with preschoolers or scaffold their learning. Rather, when children imitate adult tasks, parents conclude that they are ready for more responsibility. Then they assign chores, selecting tasks the child can do with little help so that adult work is not disturbed. If a child cannot do a task, the adult takes over and

In a South-African village, a young child intently watches his mother grind grain. Children in village and tribal cultures observe and participate in the work of their community from an early age.

the child observes, reengaging when able to contribute.

Expected to be autonomous and helpful, Yucatec Mayan children seldom display attention-getting behaviors or ask others for something interesting to do. From an early age, they can sit quietly for long periods—through a lengthy religious service or a three-hour truck ride. And when an adult interrupts their activity and directs them to do a chore, they respond eagerly to the type of command that Western children frequently avoid or resent. By age 5, Yucatec Mayan children spontaneously take responsibility for tasks beyond those assigned.

**Inhibition.** With age, preschoolers gain steadily in ability to inhibit impulses and keep their mind on a competing goal. Consider a task in which the child must tap once when the adult taps twice and tap twice when the adult taps once or must say “night” to a picture of the sun and “day” to a picture of the moon with stars. As Figure 7.8 on page 238 shows, 3- and 4-year-olds make many errors. But by age 6 to 7, children find such tasks easy (Diamond, 2004; Montgomery & Koeltzow, 2010). They can resist the “pull” of their attention toward a dominant stimulus—

a skill that, as early as age 3 to 5, predicts social maturity as well as reading and math achievement from kindergarten through high school (Blair & Razza, 2007; Duncan et al., 2007; Rhoades, Greenberg, & Domitrovich, 2009).

**Flexible Shifting.** Children's ability to flexibly shift their focus of attention, depending on what's important at the moment, is often studied through categorization and sorting behaviors. As we saw in Chapter 5, even toddlers have a beginning ability to

**FIGURE 7.8** Gains between ages 3 and 7 in performance on tasks requiring children to inhibit an impulse and focus on a competing goal. In the tapping task, children had to tap once when the adult tapped twice and tap twice when the adult tapped once. In the day–night task, children had to say “night” to a picture of the sun and “day” to a picture of the moon with stars. (From A. Diamond, 2004, “Normal Development of Prefrontal Cortex from Birth to Young Adulthood: Cognitive Functions, Anatomy, and Biochemistry,” as appeared in D. T. Stuss & R. T. Knight [Eds.], *Principles of Frontal Lobe Function*, New York: Oxford University Press, p. 474. Reprinted by permission of Adele Diamond.)

shift their basis of sorting a small set of objects after an adult calls their attention to a second way of grouping (see page 164).

In preschoolers and school-age children, flexible shifting is often studied through rule-use tasks (Zelazo et al., 2013). In this procedure, children are asked to switch the rules they use to sort picture cards in the face of conflicting cues. For example, children might first be asked to sort pictures of boats and flowers using color rules, by placing all the blue boats and flowers in a box marked with a blue boat and all the red boats and flowers in a box marked with a red flower. Then the child is asked to switch to shape rules, placing all the boats (irrespective of color) into the box marked with the blue boat and all the flowers into the box marked with the red flower. Three-year-olds persist in sorting by color; not until age 4 do children succeed in switching rules (Zelazo, 2006). And when researchers increase the complexity of the rules—for example, requiring children to shift from color to shape rules only on a subset of picture cards with an added black border—most 6-year-olds have difficulty (Henning, Spinath, & Aschersleben, 2011).

As these findings confirm, flexible shifting improves greatly during the preschool years, with gains continuing in middle childhood. Note that inhibition contributes to preschoolers’ flexible shifting (Kirkham, Cruess, & Diamond, 2003; Zelazo et al., 2013). To switch rules, children must inhibit attending to the previously relevant dimension while focusing on the dimension they had just ignored.

**Working Memory.** Gains in working memory, enabling preschoolers to hold in mind and manipulate more information at once (see page 161 in Chapter 5), contribute to control of attention. Greater working-memory capacity eases effort in

keeping several rules in mind, ignoring ones not currently important, and flexibly shifting focus to new rules, thereby improving performance.

With age, the ability to hold and combine information in working memory becomes increasingly important in problem solving. In one study, both inhibition and working-memory scores predicted 2½- to 6-year-olds’ solutions to a problem-solving task requiring multistep planning. But working memory was a stronger predictor for the 4- to 6-year-olds than for the younger children (Senn, Espy, & Kaufmann, 2004). Older preschoolers were able to deploy their larger working memories to solve more challenging problems involving planning.

**Planning.** As the findings just described suggest, early childhood is a time of marked gains in *planning*—thinking out a sequence of acts ahead of time and performing them accordingly to reach a goal. Because successful planning requires that basic executive processes be integrated with other cognitive operations, it is regarded as a complex executive function activity (Müller & Kerns, 2015). As long as tasks are not too difficult, older preschoolers can follow a plan.

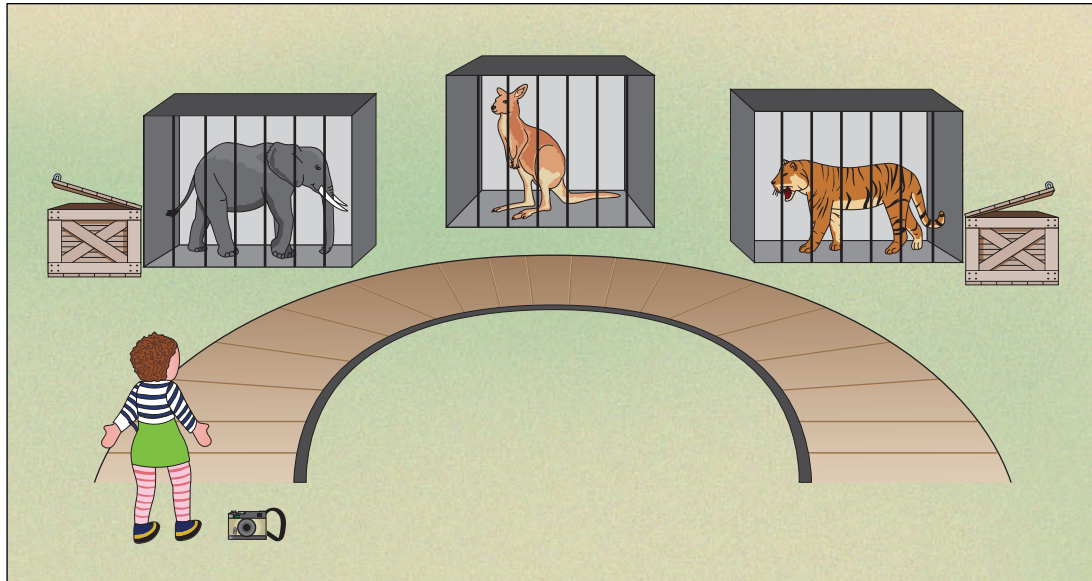

Consider a task, devised to resemble real-world planning, in which 3- to 5-year-olds were shown a doll named Molly, a camera, and a miniature zoo with a path, along which were three animal cages. The first and third cages had storage lockers next to them; the middle cage, with no locker, housed a kangaroo (see Figure 7.9). The children were told that Molly could follow the path only once and that she wanted to take a picture of the kangaroo. Then they were asked, “What locker could you leave the camera in so Molly can get it and take a photo of the kangaroo?” (McColgan & McCormack, 2008). Not until age 5 were children able to plan effectively, selecting the locker at the first cage.

On this and other planning tasks, young preschoolers have difficulty (McCormack & Atance, 2011). By the end of early childhood, children make strides in postponing action in favor of mapping out a sequence of future moves, evaluating the consequences of each, and adjusting their plan to fit task requirements.

### Parenting and Development of Executive Function.

Parental sensitivity and scaffolding foster preschoolers’ executive function skills, as many investigations reveal (Carlson, Zelazo, & Faja, 2013). In one study, parental scaffolding of 2- and 3-year-olds while jointly solving a challenging puzzle predicted higher scores on diverse executive function tasks at age 4 (Hammond et al., 2012). Among the 2-year-olds, effective scaffolding led to gains in language, which in turn promoted executive function, perhaps by augmenting children’s ability to verbally regulate their behavior through private speech.

With respect to planning, children learn much from cultural tools that support it—directions for playing games, patterns for construction, recipes for cooking—especially when they collaborate with expert planners. When mothers were observed constructing a toy with their 4- to 7-year-olds, they often pointed out the usefulness of plans and how to implement specific steps: “Do

**FIGURE 7.9** Miniature zoo used to assess children’s planning. After having been told that Molly wanted to take a picture of the kangaroo but could follow the path only once, preschoolers were asked which locker the camera should be left in so Molly could get it and take the photo. Not until age 5 did children plan, more often selecting the first locker. (Based on McColgan & McCormack, 2008.)

you want to look at the picture and see what goes where? What piece do you need first?” After working with their mothers, younger children more often referred to the plan while building on their own (Gauvain, de la Ossa, & Hurtado-Ortiz, 2001). When parents encourage planning in everyday activities, from loading the dishwasher to packing for a vacation, they help children plan more effectively.

Poverty exerts a negative impact on executive function, in part through maladaptive parenting practices and chronic stress. In a socioeconomically and ethnically diverse sample, poverty-stricken mothers more often interacted harshly and intrusively with their 7- to 24-month-olds—parenting behaviors associated

with children’s elevated cortisol levels and with poor executive function scores during a follow-up at age 3 (Blair et al., 2011). As the authors noted, poverty and negative parenting undermined early stress regulation, promoting “reactive and inflexible rather than reflective and flexible forms of behavior and cognition” (p. 1980).

## Memory

Unlike infants and toddlers, preschoolers have the language skills to describe what they remember, and they can follow directions on memory tasks. As a result, memory becomes easier to study in early childhood. The memory changes of the first two years are largely *implicit*, taking place without conscious awareness. This enables researchers to focus on *explicit*, or conscious, memory which undergoes the greatest change throughout development.

**Recognition and Recall.** Show a young child a set of 10 pictures or toys. Then mix them up with some unfamiliar items, and ask the child to point to the ones in the original set. You will find that preschoolers’ *recognition* memory—ability to tell whether a stimulus is the same as or similar to one they have seen before—is remarkably good. In fact, 4- and 5-year-olds perform nearly perfectly.

Now keep the items out of view, and ask the child to name the ones she saw. This more demanding task requires *recall*—generating a mental image of an absent stimulus. Young children’s recall is much poorer than their recognition. At age 2, they can recall no more than one or two items and at age 4 only about three or four (Perlmutter, 1984).

© LAURA DWIGHT PHOTOGRAPHY

A grandfather engages in scaffolding by breaking a challenging construction task into manageable units and suggesting strategies to his 3-year-old grandchild—support that consistently promotes diverse executive function skills.

Improvement in recall in early childhood is strongly associated with language development, which greatly enhances long-lasting representations of past experiences (Melby-Lervag & Hulme, 2010). But even preschoolers with good language skills recall poorly because they are not skilled at using **memory strategies**—deliberate mental activities that improve our chances of remembering. Preschoolers do not yet *rehearse*, or repeat items over and over, to remember. Nor do they *organize*, intentionally grouping items that are alike (all the animals together, all the vehicles together) so they can easily retrieve those items by thinking of their similar characteristics—even after they are trained to do so (Bauer, 2013).

Why do young children seldom use memory strategies? One reason is that strategies tax their limited working memories. Preschoolers have difficulty holding on to pieces of information and applying a strategy at the same time.

**Memory for Everyday Experiences.** Think about the difference between your recall of listlike information and your memory for everyday experiences—what researchers call **episodic memory**. In remembering everyday experiences, you recall information in context—linked to a particular time, place, or person. In remembering lists, you recall isolated pieces—information removed from the context in which it was first learned that has become part of your general knowledge base. Researchers call this type of memory **semantic memory**.

Between 3 and 6 years, children improve sharply in memory for relations among stimuli. For example, in a set of photos, they remember not just the animals they saw but their contexts, such as a bear emerging from a tunnel or a zebra tied to a tree (Lloyd, Doydum, & Newcombe, 2009). The capacity to bind together stimuli supports an increasingly rich episodic memory in early childhood.

**Memory for Routine Events.** Like adults, preschoolers remember familiar, repeated events—what you do when you go to preschool or have dinner—in terms of **scripts**, general descriptions of what occurs and when it occurs in a particular situation. Young children’s scripts begin as a structure of main acts. For example, when asked to tell what happens at a restaurant, a 3-year-old might say, “You go in, get the food, eat, and then pay.” Although children’s first scripts contain only a few acts, they are almost always recalled in correct sequence (Bauer, 2006, 2013). With age, scripts become more elaborate, as in this 5-year-old’s account of going to a restaurant: “You go in. You can sit in a booth or at a table. Then you tell the waitress what you want. You eat. If you want dessert, you can have some. Then you pay and go home” (Hudson, Fivush, & Kuebli, 1992).

Scripts help children (and adults) organize and interpret routine experiences. Once formed, scripts can be used to predict what will happen in the future. Children rely on scripts in make-believe play and when listening to and telling stories. Scripts also support children’s earliest efforts at planning by helping them represent sequences of actions that lead to desired goals (Hudson & Mayhew, 2009).

**Memory for One-Time Events.** In Chapter 5, we considered a second type of episodic memory—*autobiographical memory*, or representations of personally meaningful, one-time events. As preschoolers’ cognitive and conversational skills improve, their descriptions of special events become better organized in time, more detailed, enriched with a personal perspective, and related to the larger context of their lives. A young preschooler simply reports, “I went camping.” Older preschoolers include specifics: where and when the event happened and who was present. And with age, preschoolers increasingly include subjective information that explains the event’s personal significance (Bauer, 2013; Pathman et al., 2013). For example, they might say, “I loved sleeping all night in the tent.”

Adults use two styles to elicit children’s autobiographical narratives. In the *elaborative style*, they follow the child’s lead, ask varied questions, add information to the child’s statements, and volunteer their own recollections and evaluations of events, assisting the child in weaving together a story. For example, after a trip to the zoo, the parent might say, “What was the first thing we did? Why weren’t the parrots in their cages? I thought the lion was scary. What did you think?” In contrast, adults who use the *repetitive style* provide little information and keep repeating the same questions: “Do you remember the zoo? What did we do at the zoo?” Elaborative-style parents *scaffold* the autobiographical memories of their young children, who produce more organized and detailed personal stories when followed up later in childhood and in adolescence (Reese, 2002).

As children talk with adults about the past, they not only improve their autobiographical memory but also create a shared history that strengthens close relationships and self-understanding. Parents and preschoolers with secure attachment bonds engage in more elaborate reminiscing (Bost et al., 2006). And 5- and 6-year-olds of elaborative-style parents describe themselves in clearer, more consistent ways (Bird & Reese, 2006).

© ROBERT BRENNER/PHOTOEDIT

As this toddler talks with his mother about past experiences, she responds in an elaborative style, asking varied questions and contributing her own recollections. Through such conversations, she enriches his autobiographical memory.

Girls tend to produce more organized and detailed personal narratives than boys. Compared with Asian children, Western children produce narratives with more talk about their own thoughts and emotions. These differences fit with variations in parent–child conversations. Parents reminisce in greater detail and talk more about the emotional significance of events with daughters (Fivush & Zaman, 2014). And cultural valuing of an interdependent self leads many Asian parents to discourage children from talking about themselves (Fivush & Wang, 2005).

Consistent with these early experiences, women report an earlier age of first memory and more vivid early memories than men. And Western adults' autobiographical memories include earlier, more detailed events that focus more on their own roles than do the memories of Asians, who tend to highlight the roles of others (Wang, 2008).

## The Young Child's Theory of Mind

As representation of the world, memory, and problem solving improve, children start to reflect on their own thought processes. They begin to construct a *theory of mind*, or coherent set of ideas about mental activities. This understanding is also called **metacognition**, or “thinking about thought” (the prefix *meta-* means “beyond” or “higher”). As adults, we have a complex appreciation of our inner mental worlds, which we use to interpret our own and others' behavior and to improve our performance on various tasks. How early are children aware of their mental lives, and how complete and accurate is their knowledge?

**Awareness of Mental Life.** At the end of the first year, babies view people as intentional beings who can share and influence one another's mental states, a milestone that opens the door to new forms of communication—joint attention, social referencing, preverbal gestures, and spoken language. These early milestones serve as the foundation for later mental understandings.

As they approach age 2, children display a clearer grasp of others' emotions and desires, evident in their realization that people often differ from one another and from themselves in likes, dislikes, wants, needs, and wishes. As 2-year-olds' vocabularies expand, their first verbs include such words as *want*, *think*, *remember*, and *pretend* (Wellman, 2011).

By age 3, children realize that thinking takes place inside their heads and that a person can think about something without seeing, touching, or talking about it (Flavell, Green, & Flavell, 1995). But 2- to 3-year-olds' verbal responses indicate that they assume people always behave in ways consistent with their *desires*. Not until age 4 do most realize that less obvious, more interpretive mental states, such as *beliefs*, also affect behavior.

Dramatic evidence for this advance comes from games that test whether preschoolers realize that *false beliefs*—ones that do not represent reality accurately—can guide people's actions. For example, show a child two small closed boxes—a familiar Band-Aid box and a plain, unmarked box (see Figure 7.10). Then say,

**FIGURE 7.10** Example of a false-belief task. (a) An adult shows a child the contents of a Band-Aid box and of an unmarked box. The Band-Aids are in the unmarked container. (b) The adult introduces the child to a hand puppet named Pam and asks the child to predict where Pam would look for the Band-Aids and to explain Pam's behavior. The task reveals whether children understand that without having seen that the Band-Aids are in the unmarked container, Pam will hold a false belief.

“Pick the box you think has the Band-Aids in it.” Children usually pick the marked container. Next, open the boxes and show the child that, contrary to her own belief, the marked one is empty and the unmarked one contains the Band-Aids. Finally, introduce the child to a hand puppet and explain, “Here's Pam. She has a cut, see? Where do you think she'll look for Band-Aids? Why would she look in there? Before you looked inside, did you think that the plain box contained Band-Aids? Why?” (Bartsch & Wellman, 1995). Only a handful of 3-year-olds can explain Pam's—and their own—false beliefs, but many 4-year-olds can.

Some researchers claim that the procedures just described, which require verbal responses, underestimate younger children's ability to attribute false beliefs to others. For example, in a study relying on active behavior (helping), most 18-month-olds—after observing an adult reach for a box previously used for blocks that now contained a spoon—based their choice of how to help on her false belief about the contents of the box: They gave her a block rather than a spoon (Buttelmann et al., 2014). This suggests that toddlers *implicitly* understand that people's actions can be guided by false beliefs, though more evidence is needed to confirm this conclusion (Astington & Hughes, 2013). Researchers cannot yet explain the striking contrast between toddlers' success on nonverbal tasks and 3-year-olds' consistent failure on verbal assessments.

Among children of diverse cultural and SES backgrounds, *explicit* false-belief understanding strengthens after age 3½, becoming more secure between ages 4 and 6 (Wellman, 2012). During that time, it becomes a powerful tool for reflecting on the thoughts and emotions of oneself and others and a good predictor of social skills (Hughes, Ensor, & Marks, 2010). It is also associated with early reading ability, probably because it helps children comprehend story narratives (Astington & Pelletier, 2005). Following a story line often requires children to link plot actions with characters' motives and beliefs.

**Factors Contributing to Preschoolers' Theory of Mind.** How do children develop a theory of mind at such a young age? Language, executive function, make-believe play, and social experiences all contribute.

Many studies indicate that language ability strongly predicts preschoolers' false-belief understanding (Milligan, Astington, & Dack, 2007). Children who spontaneously use, or who are trained to use, mental-state words in conversation are especially likely to pass false-belief tasks (Hale & Tager-Flusberg, 2003; San Juan & Astington, 2012). Among the Quechua people of the Peruvian highlands, whose language lacks mental-state terms, children have difficulty with false-belief tasks for years after children in industrialized nations have mastered them (Vinden, 1996).

Several aspects of preschoolers' executive function—inhibition, flexible shifting of attention, and planning—predict mastery of false belief because they enhance children's ability to reflect on experiences and mental states (Benson et al., 2013; Drayton, Turley-Ames, & Guajardo, 2011; Müller et al., 2012). Inhibition is strongly related to false-belief understanding, perhaps because false-belief tasks require suppression of an irrelevant response—the tendency to assume that others' knowledge and beliefs are the same as one's own (Carlson, Moses, & Claxton, 2004).

Social experiences also made a difference. In longitudinal research, the maternal “mind-mindedness” experienced by securely attached babies (frequent commentary on their mental states) is positively associated with later performance on false-belief and other theory-of-mind tasks (Laranjo et al., 2010; Meins et al., 2003; Ruffman et al., 2006). Securely attached children also experience more elaborative parent-child narratives, including discussions of mental states (Ontai & Thompson, 2008). These conversations expose preschoolers to concepts and language that help them think about their own and others' mental lives.

Also, preschoolers with siblings who are children (but not infants)—especially those with older siblings or two or more siblings—tend to be more aware of false belief because they are exposed to more family talk about varying thoughts, beliefs, and emotions (Hughes et al., 2010; McAlister & Peterson, 2006, 2007). Similarly, preschool friends who often engage in mental-state talk—as children do during make-believe play—are advanced in false-belief understanding (de Rosnay & Hughes, 2006). These exchanges offer children extra opportunities to talk about inner states, receive feedback, and become increasingly aware of their own and others' mental activities.

Core knowledge theorists (see Chapter 5, page 158) believe that to profit from the social experiences just described, children must be biologically prepared to develop a theory of mind. Children with *autism*, for whom mastery of false belief is either greatly delayed or absent, are deficient in the brain mechanism that enables humans to detect mental states. See the Biology and Environment box on the following page to find out more about the biological basis of reasoning about the mind.

**Limitations of the Young Child's Understanding of Mental Life.** Though surprisingly advanced, preschoolers' awareness of mental activities is far from complete. For example,

3- and 4-year-olds are unaware that people continue to think while they wait, look at pictures, listen to stories, or read books—that is, when there are no obvious cues that they are thinking (Eisbach, 2004; Flavell, Green, & Flavell, 1995, 2000). Furthermore, children younger than age 6 pay little attention to the *process* of thinking. When asked about subtle distinctions between mental states, such as *know* and *forget*, they express confusion (Lyon & Flavell, 1994). And they often insist that all events must be directly observed to be known. They do not understand that *mental inferences* can be a source of knowledge (Miller, Hardin, & Montgomery, 2003).

These findings suggest that preschoolers view the mind as a passive container of information. As they move into middle childhood, they will increasingly see it as an active, constructive agent—a change we will consider further in Chapter 9.

## Early Childhood Literacy

One week, Leslie's students created a make-believe grocery store. They brought empty food boxes from home, placed them on shelves in the classroom, labeled items with prices, and wrote checks at the cash register. A sign at the entrance announced the daily specials: “APLS BNS 5¢” (“apples bananas 5¢”).

As such play reveals, preschoolers understand a great deal about written language long before they learn to read or write in conventional ways. This is not surprising: Children in industrialized nations live in a world filled with written symbols. Each day, they observe and participate in activities involving storybooks, calendars, lists, and signs. Children's active efforts to construct literacy knowledge through informal experiences are called **emergent literacy**.

Young preschoolers search for units of written language as they “read” memorized versions of stories and recognize familiar signs (“PIZZA”). But they do not yet understand the symbolic

Preschoolers acquire literacy knowledge by participating in everyday activities involving written symbols. These young chefs “write down” orders they need to fill.

## Biology and Environment

### Autism and Theory of Mind

Michael stood at the water table in Leslie's classroom, repeatedly filling a plastic cup and dumping out its contents—dip—splash, dip—splash—until Leslie came over and redirected his actions. Without looking at Leslie's face, Michael moved to a new repetitive pursuit: pouring water from one cup into another and back again. As other children entered the play space and conversed, Michael hardly noticed. He rarely spoke, and when he did, he usually used words to get things he wanted, not to exchange ideas.

Michael has *autism* (a term meaning “absorbed in the self”). Autism varies in severity along a continuum, called *autism spectrum disorder*. Michael's difficulties are substantial. Like other similarly affected children, by age 3 he displayed deficits in two core areas of functioning. First, he had only limited ability to engage in social interaction—evident in his difficulty with non-verbal communication, such as eye gaze, facial expressions, gestures, imitation, and give-and-take, and in his delayed and stereotyped language. Second, his interests were narrow and overly intense. For example, one day he sat for more than an hour spinning a toy Ferris wheel. And Michael showed another typical feature of autism: He engaged in much less make-believe play than other children (American Psychiatric Association, 2013; Tager-Flusberg, 2014).

Researchers agree that autism stems from abnormal brain functioning, usually due to genetic or prenatal environmental causes. Beginning in the first year, children with the disorder have larger-than-average brains, with the greatest excess in brain-region volume in the prefrontal cortex (Courchesne et al., 2011). This brain overgrowth is believed to result from lack of synaptic pruning, which accompanies typical development of cognitive, language, and communication skills. Furthermore, preschoolers with autism show a deficient left-hemispheric response to speech sounds (Eyler, Pierce, & Courchesne, 2012). Failure of the left hemisphere of the cerebral

cortex to lateralize for language may underlie these children's language deficits.

The amygdala, devoted to emotion processing (see page 192 in Chapter 6), also grows abnormally large in childhood, followed by a greater than average reduction in size in adolescence and adulthood. This deviant growth pattern is believed to contribute to deficits in emotion processing involved in the disorder (Allely, Gillberg, & Wilson, 2014). fMRI studies reveal that autism is associated with weaker connections between the amygdala and the temporal lobes, which are important for interpreting facial expressions (Monk et al., 2010).

Mounting evidence reveals that children with autism are impaired in theory of mind. As early as the first two years, they show deficits in emotional and social capacities believed to contribute to an understanding of mental life, including interest in observing people's actions, joint attention, and social referencing (Chawarska, Macari, & Shic, 2013; Warreyn, Roeyers, & De Groote, 2005). Long after they reach the intellectual level of an average 4-year-old, they have great difficulty with false belief. Most find it hard to attribute mental states to themselves or others (Steele, Joseph, & Tager-Flusberg, 2003). They rarely use mental-state words such as *believe*, *think*, *know*, *feel*, and *pretend*.

Do these findings indicate that autism is due to impairment in an innate, core brain function that leaves the child unable to detect others' mental states and therefore deficient in human sociability? Some researchers think so (Baron-Cohen, 2011; Baron-Cohen & Belmonte, 2005). But others point out that individuals with general intellectual disability but not autism also do poorly on tasks

© ELLEN B. SENISI

This child, who has autism, is barely aware of his teacher and classmates. Researchers disagree on whether the deficient emotional and social capacities of autism result from a basic impairment in ability to detect others' mental states, a deficit in executive function, or a style of information processing that focuses on parts rather than coherent wholes.

assessing mental understanding (Yirmiya et al., 1998). This suggests that cognitive deficits are largely responsible.

One hypothesis with growing research support is that children with autism are impaired in executive function (Kimhi et al., 2014; Pugliese et al., 2016). This leaves them deficient in skills involved in flexible, goal-oriented thinking, including shifting attention to relevant aspects of a situation, inhibiting irrelevant responses, applying strategies, and generating plans (Robinson et al., 2009).

Another possibility is that children with autism display a peculiar style of information processing, preferring to process the parts of stimuli over coherent wholes (Booth & Happé, 2016). Deficits in thinking flexibly and in holistic processing of stimuli would each interfere with understanding the social world because social interaction requires quick integration of information from various sources and evaluation of alternative possibilities.

It is not clear which of these hypotheses is correct. Perhaps several biologically based deficits underlie the tragic social isolation of children like Michael.

function of the elements of print (Bialystok & Martin, 2003). Many preschoolers think that a single letter stands for a whole word or that each letter in a person's signature represents a separate name. Children revise these ideas as their cognitive capacities improve, as they encounter writing in many contexts, and as adults help them with written communication. Gradually, they notice more features of written language and depict writing that varies in function, as in one child's horizontal line of letters to represent "a story" and vertical line to represent a "grocery list."

Eventually, children figure out that letters are parts of words and are linked to sounds in systematic ways, as 5- to 7-year-olds' invented spellings illustrate. At first, children rely on sounds in the names of letters: "ADE LAFWTS KRMD NTU A LAVATR" ("eighty elephants crammed into a[n] elevator"). Over time, they grasp sound-letter correspondences and learn that some letters have more than one common sound and that context affects their use (McGee & Richgels, 2012).

Literacy development builds on a broad foundation of spoken language and knowledge about the world (Dickinson, Golinkoff, & Hirsh-Pasek, 2010). **Phonological awareness**—the ability to reflect on and manipulate the sound structure of spoken language, as indicated by sensitivity to changes in sounds within words, to rhyming, and to incorrect pronunciation—is a strong predictor of emergent literacy knowledge and later reading and spelling achievement (Dickinson et al., 2003; Paris & Paris, 2006). When combined with sound-letter knowledge, it enables children to isolate speech segments and link them with their written symbols. Vocabulary and grammatical knowledge are also influential. And narrative competence, assessed by having preschoolers retell stories, fosters diverse language skills essential for literacy progress, including phonological awareness (Hipfner-Boucher et al., 2014). Coherent storytelling requires attention to large language structures, such as character, setting, problem, and resolution. This seems to support the smaller-scale analysis involved in awareness of sound structures.

The more informal literacy experiences young children have, the better their language and literacy development (Dickinson & McCabe, 2001; Speece et al., 2004). Pointing out letter-sound correspondences and playing language-sound games enhance children's awareness of the sound structures of language and how they are represented in print (Ehri & Roberts, 2006). *Interactive reading*, in which adults discuss storybook content with preschoolers, and adult-supported writing activities that focus on narrative, such as preparing a letter or a story, also have wide-ranging benefits (Hood, Conlon, & Andrews, 2008; Senechal & LeFevre, 2002; Storch & Whitehurst, 2001). Each is linked to improved reading achievement in middle childhood.

Preschoolers from low-SES families have far fewer home and preschool language and literacy learning opportunities—a gap that translates into large differences in reading readiness at kindergarten entry (see Figure 7.11) and into widening disparities in reading achievement during the school years (Cabell et al., 2013; Hoff, 2013). But high-quality intervention can reduce the SES gap in early literacy development substantially. Providing low-SES parents with children's books, along with guidance in how to stimulate emergent literacy, greatly enhances literacy

**FIGURE 7.11** Some reading readiness skills at kindergarten entry by SES. The SES gap in emergent literacy development is large. (Adapted from Lee & Burkam, 2002.)

activities in the home (Huebner & Payne, 2010). And when teachers are shown how to engage in effective instruction of diverse literacy skills, low-SES preschoolers gain in emergent literacy components included in their classroom experiences (Hilbert & Eis, 2014; Lonigan et al., 2013).

## Early Childhood Mathematical Reasoning

Mathematical reasoning, like literacy, builds on informally acquired knowledge. Between 14 and 16 months, toddlers display a beginning grasp of **ordinality**, or order relationships between quantities—for example, that 3 is more than 2, and 2 is more than 1. In the early preschool years, children attach verbal labels (*lots, little, big, small*) to amounts and sizes. Sometime in the third year, they begin to count. By the time children turn 3, most can count a row of about five objects, although they do not yet know exactly what the words mean. For example, when asked for *one*, they give one item, but when asked for *two, three, four, or five*, they usually give a larger, but incorrect, amount. Nevertheless, 2½- to 3½-year-olds realize that a number word refers to a unique quantity (Sarnecka & Gelman, 2004). They know that when a number label changes (for example, from *five* to *six*), the number of items should also change.

By age 3½ to 4, most children have mastered the meaning of numbers up to 10, count correctly, and grasp the vital principle of **cardinality**—that the last number in a counting sequence indicates the quantity of items in a set (Sarnecka & Wright, 2013). Mastery of cardinality increases the efficiency of children's counting.

Around age 4, children use counting to solve simple arithmetic problems. At first, their strategies are tied to the order of numbers as presented; to add  $2 + 4$ , they count on from 2 (Bryant & Nunes, 2002). But soon they experiment with other strategies and eventually arrive at the most efficient, accurate approach—

© ELLEN B. SENISI

Preschoolers “hop” a toy frog along a number line, measuring the length of each jump. Through informal exploration of number concepts, they construct basic understandings essential for learning math skills later on.

in this example, beginning with the higher digit. Around this time, children realize that subtraction cancels out addition. Knowing, for example, that  $4 + 3 = 7$ , they can infer without counting that  $7 - 3 = 4$  (Rasmussen, Ho, & Bisanz, 2003). Grasping basic arithmetic rules facilitates rapid computation, and with enough practice, children recall answers automatically.

When adults provide many occasions for counting, comparing quantities, and talking about number concepts, children acquire these understandings sooner (Ginsburg, Lee, & Boyd, 2008). Math proficiency at kindergarten entry predicts math achievement years later, in elementary and secondary school (Duncan et al., 2007; Romano et al., 2010).

As with emergent literacy, children from low-SES families begin kindergarten with considerably less math knowledge than their economically advantaged agemates—a gap due to differences in home learning environments (DeFlorio & Beliakoff, 2015). In an early childhood math curriculum called *Building Blocks*, materials that promote math concepts and skills through three types of media—computers, manipulatives, and print—enable teachers to weave math into many preschool daily activities, from building blocks to art and stories (Clements et al., 2011). Compared with agemates randomly assigned to other preschool programs, low-SES preschoolers experiencing Building Blocks showed substantially greater year-end gains in math concepts and skills, including counting, sequencing, and arithmetic computation.

## Ask yourself

**CONNECT** Cite evidence on the development of preschoolers’ memory, theory of mind, executive function, and literacy and mathematical understanding that is consistent with Vygotsky’s sociocultural theory.

**APPLY** Lena wonders why her 4-year-old son Gregor’s teacher provides extensive playtime in learning centers during each preschool day. Explain to Lena how adult-supported play can promote literacy and math skills essential for academic success.

**REFLECT** Describe informal experiences important for literacy and math development that you experienced while growing up.

## Individual Differences in Mental Development

**7.13** Describe early childhood intelligence tests and the impact of home, preschool and kindergarten programs, child care, and educational media on mental development.

Five-year-old Hal sat in a testing room while Sarah gave him an intelligence test. Some of Sarah’s questions were *verbal*. For example, she showed Hal a picture of a shovel and said, “Tell me what this is”—an item measuring vocabulary. She tested his working memory by asking him to repeat sentences and lists of numbers back to her. She probed his quantitative knowledge and problem solving by seeing if he could count and solve simple addition and subtraction problems. To assess Hal’s spatial reasoning, Sarah used *nonverbal* tasks: Hal copied designs with special blocks, figured out the pattern in a series of shapes, and indicated what a piece of paper folded and cut would look like when unfolded (Roid, 2003; Wechsler, 2012).

Sarah knew that Hal came from an economically disadvantaged family. When low-SES and certain ethnic minority preschoolers are bombarded with questions by an unfamiliar adult, they sometimes react with anxiety. Also, such children may not define the testing situation in achievement terms (Ford, Kozey, & Negreiros, 2012). Instead, they may look for attention and approval from the adult and may settle for lower performance than their abilities allow. Sarah spent time playing with Hal before she began testing and encouraged him while testing was in progress (Bracken & Nagle, 2006). Under these conditions, low-SES preschoolers improve in performance.

The questions Sarah asked Hal tap knowledge and skills that not all children have equal opportunity to learn. In Chapter 9, we will take up the hotly debated issue of *cultural bias* in mental testing. For now, keep in mind that intelligence tests do not sample all human abilities, and cultural and situational factors affect performance. Nevertheless, test scores remain important: By age 6 to 7, they are good predictors of later IQ and academic achievement, which are related to vocational success in industrialized societies. Let’s see how the environments in which preschoolers spend their days—home, preschool, and child care—affect mental test performance.

## Home Environment and Mental Development

A special version of the *Home Observation for Measurement of the Environment (HOME)*, covered in Chapter 5, assesses aspects of 3- to 6-year-olds’ home lives that foster intellectual growth. Research with the HOME early childhood subscales reveals that preschoolers who develop well intellectually have homes rich in educational toys and books. Their parents are warm and affectionate, stimulate language and academic knowledge, and arrange interesting outings. They also make reasonable demands for socially mature behavior—for example, that the child perform simple chores and behave courteously toward others. And

these parents resolve conflicts with reason instead of physical force and punishment (Bradley & Caldwell, 1982; Espy, Molfese, & DiLalla, 2001; Roberts, Burchinal, & Durham, 1999).

When low-SES parents manage, despite life challenges, to obtain high HOME scores, their preschoolers do substantially better on tests of intelligence and measures of language and emergent literacy skills (Berger, Paxson, & Waldfogel, 2009; Mistry et al., 2008). In a study of African-American 3- and 4-year-olds from low-income families, HOME cognitive stimulation and emotional support subscales predicted reading achievement four years later (Zaslow et al., 2006). These findings highlight the vital contribution of home environmental quality to children's overall intellectual development.

## Preschool, Kindergarten, and Child Care

Children between ages 2 and 6 spend even more time away from their homes and parents than infants and toddlers do. Largely because of the rise in maternal employment, over the past several decades the number of young children enrolled in preschool or child care has steadily increased to more than 65 percent in the United States (U.S. Census Bureau, 2015d).

A *preschool* is a program with planned educational experiences aimed at enhancing the development of 2- to 5-year-olds. In contrast, *child care* refers to a variety of arrangements for supervising children, from care in the caregiver's or the child's home to a center-based program. The line between preschool and child care is fuzzy. Parents often select a preschool as a child-care option. And in response to the needs of employed parents, many U.S. preschools, as well as most public school kindergartens, have increased their hours from half to full days (Child Trends, 2015b).

With age, preschoolers tend to shift from home-based to center-based programs. In the United States, children of higher-income parents and children of very-low-income parents are especially likely to be in preschools or child-care centers (Child Trends, 2015b). Many low-income working parents rely on care by relatives because they are not eligible for public preschool or government-subsidized child-care centers. A few states offer government-funded prekindergarten programs located within public schools to all 4-year-olds. The goal of these universal pre-kindergartens is to ensure that as many children as possible, from all SES levels, enter kindergarten prepared to succeed.

**Types of Preschool and Kindergarten.** Preschool and kindergarten programs range along a continuum from child-centered to teacher-directed. In **child-centered programs**, teachers provide activities from which children select, and much learning takes place through play. In contrast, in **academic programs**, teachers structure children's learning, teaching letters, numbers, colors, shapes, and other academic skills through formal lessons, often using repetition and drill.

Despite evidence that formal academic training undermines young children's motivation and emotional well-being, early

childhood teachers have felt increased pressure to take this approach. Preschoolers and kindergartners who spend much time in large-group, teacher-directed academic instruction and completing worksheets—as opposed to being actively engaged in learning centers by warm, responsive teachers—display more stress behaviors (such as wiggling and rocking), have less confidence in their abilities, prefer less challenging tasks, and are less advanced in motor, academic, language, and social skills at the end of the school year (Stipek, 2011; Stipek et al., 1995). Follow-ups reveal lasting effects through elementary school in poorer study habits and achievement (Burts et al., 1992; Hart et al., 1998, 2003). These outcomes are strongest for low-SES children.

Although government spending for universal prekindergarten is controversial in the United States, in Western Europe such programs are widespread and child-centered in their daily activities. Enrolled preschoolers of all SES backgrounds show gains in cognitive and social development still evident in elementary and secondary school (Rindermann & Ceci, 2008; Waldfogel & Zhai, 2008). Findings on some U.S. universal prekindergarten programs that meet rigorous state standards of quality—especially, provision of rich teacher-child interactions and stimulating learning activities—reveal up to a one-year advantage in kindergarten and first-grade language, literacy, and math scores relative to those of children not enrolled (Gormley & Phillips, 2009; Weiland & Yoshikawa, 2013). Children from low-SES families benefit most.

As for the dramatic rise in full-day kindergartens, the longer school day is associated with better academic achievement through elementary school. But benefits for social development are mixed (Brownell et al., 2015; Cooper et al., 2010). Some evidence suggests that kindergartners in full-day as opposed to half-day classrooms have more behavior problems.

**Early Intervention for At-Risk Preschoolers.** In the 1960s, as part of the “War on Poverty” in the United States, many intervention programs for low-SES preschoolers were initiated in an effort to address learning problems prior to school entry. The most extensive of these federal programs, **Project Head Start**, began in 1965. A typical Head Start center provides children with a year or two of preschool, along with nutritional and health services. Parent involvement is central to the Head Start philosophy. Parents serve on policy councils, contribute to program planning, work directly with children in classrooms, attend special programs on parenting and child development, and receive services directed at their own emotional, social, and vocational needs. Currently, Head Start serves about 904,000 children and their families across the nation (Office of Head Start, 2014).

More than two decades of research have established the long-term benefits of preschool intervention. The most extensive study combined data from seven programs implemented by universities or research foundations. Results showed that poverty-stricken children who attended programs scored higher in IQ and achievement than controls during the first 2 to 3 years of elementary school. After that, differences declined (Lazar & Darlington,

1982). But on real-life measures of school adjustment, children and adolescents who had received intervention remained ahead. They were less likely to be placed in special education or retained in grade, and a greater number graduated from high school.

A separate report on one program—the High/Scope Perry Preschool Project—revealed benefits lasting well into adulthood. Two years' exposure to cognitively enriching preschool was associated with increased employment and reduced pregnancy and delinquency rates in adolescence. At age 27, those who had attended preschool were more likely than their no-preschool counterparts to have earned both high school and college degrees, have higher incomes, be married, and own their own home—and less likely to have been involved with the criminal justice system. In the most recent follow-up, at age 40, the intervention group sustained its advantage on all measures of life success, including education, income, family life, and law-abiding behavior (Schweinhart, 2010; Schweinhart et al., 2005).

Do effects on school adjustment of these excellent interventions generalize to Head Start and other community-based preschool interventions? Gains are similar, though not as strong. Head Start preschoolers, who are more economically disadvantaged than children in other programs, have more severe learning and behavior problems. And quality of Head Start—though better than in most preschool programs serving low-SES children—often does not equal that of model university-based programs (Barnett, 2011; Resnick, 2010). But community-based interventions of high quality are associated with diverse life-success outcomes, including higher rates of high school graduation and college enrollment and lower rates of adolescent drug use and delinquency (Yoshikawa et al., 2013).

A consistent finding is that gains in IQ and achievement test scores from attending Head Start and other interventions quickly dissolve. In the Head Start Impact Study, a nationally representative sample of 5,000 Head Start–eligible 3- and 4-year-olds was randomly assigned to one year of Head Start or to a control group that could attend other types of preschool programs (Puma et al., 2012; U.S. Department of Health and Human Services, 2010). By year's end, Head Start 3-year-olds exceeded controls in vocabulary, emergent literacy, and math skills; 4-year-olds in vocabulary, emergent literacy, and color identification. But except for language skills, academic test-score advantages were no longer evident by the end of first grade. And Head Start graduates did not differ from controls on any achievement measures at the end of third grade.

What explains these disappointing results? Head Start children typically enter inferior public schools in poverty-stricken neighborhoods, which undermine the benefits of preschool education (Ramey, Ramey, & Lanzi, 2006). And recall from Chapter 5 that when intensive intervention begins in infancy, IQ gains are more likely to endure into adulthood (see page 173).

A few supplementary programs have responded to the need to intensify preschool intervention to augment its impact. One of the most widely implemented is *Head Start REDI* (Research-Based Developmentally Informed), an enrichment curriculum designed for integration into existing Head Start classrooms.

© LAURA DWIGHT PHOTOGRAPHY

This teacher integrates Head Start REDI into her preschool classroom. By delivering extra educational enrichment, Head Start REDI yields greater gains in language, literacy, and social skills than typical Head Start classrooms.

Before school begins, Head Start teachers—60 percent of whom do not have teaching certificates—take workshops in which they learn strategies for enhancing language, literacy, and social skills. Throughout the school year, they receive one-to-one mentoring from master teachers, aimed at ensuring effective delivery of REDI.

Relative to typical Head Start classrooms, Head Start plus REDI yields higher year-end language, literacy, and social development scores—advantages still evident at the end of kindergarten (Bierman et al., 2008, 2014). REDI's impact on teaching quality is likely responsible. Teachers trained in REDI converse with preschoolers in more cognitively complex ways and more often use management strategies that prevent disruptive behavior (Domitrovich et al., 2009).

Head Start is highly cost-effective when compared to the price of providing special education, treating criminal behavior, and supporting unemployed adults. Because of limited funding, however, only 46 percent of 3- and 4-year-olds living in poverty attend preschool, with Head Start serving just half of these children (Child Trends, 2014b).

**Child Care.** We have seen that high-quality early intervention can enhance the development of economically disadvantaged children. As noted in Chapter 5, however, much U.S. child care lacks quality. Preschoolers exposed to substandard care, especially for long hours in crowded child-care centers, score lower in cognitive and social skills and display more behavior problems (Burchinal et al., 2015; NICHD Early Child Care Research Network, 2003b, 2006). Externalizing difficulties are especially likely to endure into the school years after extensive exposure to mediocre care (Belsky et al., 2007b; Vandell et al., 2010).

In contrast, good child care enhances cognitive, language, and social development, especially for low-SES children—effects that persist into elementary school and, for academic achievement, adolescence (Burchinal et al., 2015; Dearing, McCartney, & Taylor, 2009; Vandell et al., 2010). Center-based

## Applying what we Know

### Signs of Developmentally Appropriate Early Childhood Programs

PROGRAM CHARACTERISTICS	SIGNS OF QUALITY
Physical setting	Indoor environment is clean, in good repair, and well-ventilated. Classroom space is divided into richly equipped activity areas, including make-believe play, blocks, science, math, games and puzzles, books, art, and music. Fenced outdoor play space is equipped with swings, climbing equipment, tricycles, and sandbox.
Group size	In preschools and child-care centers, group size is no greater than 18 to 20 children with two teachers.
Teacher-child ratio	In preschools and child-care centers, teacher is responsible for no more than 8 to 10 children. In family child-care homes, caregiver is responsible for no more than 6 children.
Daily activities	Children select many of their own activities and learn through experiences relevant to their own lives, mainly in small groups or individually. Teachers facilitate children's involvement, accept individual differences, and adjust expectations to children's developing capacities.
Interactions between adults and children	Teachers move among groups and individuals, asking questions, offering suggestions, and adding more complex ideas. Teachers use positive guidance techniques, such as modeling and encouraging expected behavior and redirecting children to more acceptable activities.
Teacher qualifications	Teachers have college-level specialized preparation in early childhood development, early childhood education, or a related field.
Relationships with parents	Parents are encouraged to observe and participate. Teachers talk frequently with parents about children's behavior and development.
Licensing and accreditation	Preschool and child-care programs are licensed by the state. Voluntary accreditation by the National Association for the Education of Young Children ( <a href="http://www.naeyc.org/academy">www.naeyc.org/academy</a> ) or the National Association for Family Child Care ( <a href="http://www.nafcc.org">www.nafcc.org</a> ) is evidence of an especially high-quality program.

Source: Copple & Bredekamp, 2009.

care is more strongly associated with cognitive gains than are other child-care arrangements (Abner et al., 2013). Good-quality child-care centers are more likely than family child-care homes to provide a systematic educational program.

Applying What We Know above summarizes characteristics of high-quality early childhood programs, based on standards for developmentally appropriate practice devised by the U.S. National Association for the Education of Young Children. These standards offer a set of worthy goals as the United States strives to upgrade child-care and educational services for young children.

## Educational Media

Besides home and preschool, young children spend much time in another learning environment: screen media, including both television and computers. In the industrialized world, nearly all homes have at least one television set, and most have two or more. And more than 90 percent of U.S. children live in homes with one or more computers, 80 percent of which have an Internet connection, usually a high-speed link (Rideout, Foehr, & Roberts, 2010; U.S. Census Bureau, 2015d).

**Educational Television.** Sammy's favorite TV program, *Sesame Street*, uses lively visual and sound effects to stress basic literacy and number concepts and puppet and human characters

to teach general knowledge, emotional and social understanding, and social skills. Today, *Sesame Street* is broadcast in more than 140 countries, making it the most widely viewed children's program in the world (Sesame Workshop, 2015).

Time devoted to watching children's educational programs, including *Sesame Street*, is associated with gains in early literacy and math skills and academic progress in elementary school (Ennemoser & Schneider, 2007; Mares & Pan, 2013). One study reported a link between preschool viewing of *Sesame Street* (and similar educational programs) and getting higher grades, reading more books, and placing more value on achievement in high school (Anderson et al., 2001).

*Sesame Street* modified its previous, rapid-paced format in favor of more leisurely episodes with a clear story line. Programs with slow-paced action and easy-to-follow narratives, such as *Arthur* and *The Magic School Bus*, are associated with improved executive function, greater recall of program content, gains in vocabulary and reading skills, and more elaborate make-believe play than programs presenting quick, disconnected bits of information (Lillard & Peterson, 2011; Linebarger & Piotrowski, 2010). Narratively structured educational TV eases processing demands, facilitating attention and freeing up space in working memory for applying program content to real-life situations.

Despite the spread of computers, television remains the dominant form of youth media. The average U.S. 2- to 6-year-old watches TV programs and videos from 1½ to 2⅔ hours a day. In

middle childhood, viewing time increases to an average of 3½ hours a day and then declines slightly in adolescence (Common Sense Media, 2013; Rideout, Foehr, & Roberts, 2010).

Low-SES children are more frequent TV viewers, perhaps because few alternative forms of entertainment are available in their neighborhoods or affordable for their parents. On the positive side, preschoolers in low-SES families watch as much educational television as their economically advantaged agetates (Common Sense Media, 2013). But parents with limited education are more likely to engage in practices that heighten TV viewing of all kinds, including leaving the TV on all day and eating family meals in front of it (Rideout, Foehr, & Roberts, 2010).

About 35 percent of U.S. preschoolers and 45 percent of school-age children have a TV set in their bedroom. These children are exposed to even more background TV than their agetates and spend from 40 to 90 minutes more per day watching programs, usually with no parental restrictions on what they view (Common Sense Media, 2013; Rideout & Hamel, 2006).

Does extensive TV viewing take children away from worthwhile activities? Persistent background TV distracts infants and preschoolers from their play, diminishing time spent in focused attention and involvement with a set of toys (Courage & Howe, 2010). The more preschool and school-age children watch prime-time shows and cartoons, the less time they spend reading and interacting with others and the poorer their academic skills (Ennemoser & Schneider, 2007; Huston et al., 1999; Wright et al., 2001). Whereas educational programs can be beneficial, watching entertainment TV—especially heavy viewing—detracts from children’s school success and social experiences.

**Learning with Computers.** The majority of 2- to 4-year-olds have used a computer at one time or another, and more than one-third do so regularly—from once a week to every day. But although almost all young children from higher-income families have access to a computer at home, only about half of those from low-income families do (Common Sense Media, 2013; Fletcher et al., 2014).

Because computers can have rich educational benefits, most early childhood classrooms include computer-learning centers. Computer literacy and math programs, including online storybooks, expand children’s general knowledge and encourage diverse language, literacy, and arithmetic skills (Karemaker, Pitchford, & O’Malley, 2010; Li, Atkins, & Stanton, 2006). Kindergartners who use computers to draw or write produce more elaborate pictures and text and make fewer writing errors.

Simplified computer languages that children can use to make designs or build structures introduce them to programming skills. As long as adults support children’s efforts, these activities promote problem solving and metacognition because children must plan and reflect on their thinking to get their programs to work. Furthermore, while programming, children are especially likely to help one another and to persist in the face of challenge (Resnick & Silverman, 2005; Tran & Subrahmanyam, 2013).

As with television, children spend much time using computers and other screen media for entertainment—especially

© LAURA DWIGHT PHOTOGRAPHY

In a preschool computer-learning center, children jointly play a game aimed at strengthening math concepts and problem solving. They are likely to gain in both math and collaborative skills.

game playing, which more than triples from early to middle childhood, when it consumes, on average, 1¼ hours per day. Boys are two to three times more likely than girls to be daily players (Common Sense Media, 2013; Rideout, Foehr, & Roberts, 2010). Both TV and game media are rife with gender stereotypes and violence. We will consider the impact of screen media on emotional and social development in the next chapter.

## Ask yourself

**CONNECT** Compare outcomes resulting from preschool intervention programs with those from interventions beginning in infancy (see pages 172–173 in Chapter 5). Which are more likely to lead to lasting cognitive gains? Explain.

**APPLY** Your senator has heard that IQ gains resulting from Head Start do not last, so he plans to vote against additional funding. Write a letter explaining why he should support Head Start.

**REFLECT** How much and what kinds of TV viewing and computer use did you engage in as a child? How do you think your home media environment influenced your development?

## Language Development

**7.14** Trace the development of vocabulary, grammar, and conversational skills in early childhood.

**7.15** Cite factors that support language learning in early childhood.

Language is intimately related to virtually all cognitive changes discussed in this chapter. Between ages 2 and 6, children make momentous advances in language. Their remarkable achievements, as well as their mistakes along the way, reveal their active, rule-oriented approach to mastering their native tongue.

## Vocabulary

At age 2, Sammy had a spoken vocabulary of about 250 words. By age 6, he will have acquired around 10,000 words (Byrnes & Wasik, 2009). To accomplish this feat, Sammy will learn about five new words each day. How do children build their vocabularies so quickly? Research shows that they can connect new words with their underlying concepts after only a brief encounter, a process called **fast-mapping**. Preschoolers can even fast-map two or more new words encountered in the same situation (Wilkinson, Ross, & Diamond, 2003). Still, fast-mapping does not imply that children immediately acquire adultlike word meanings.

**Types of Words.** Children in many Western and non-Western language communities fast-map labels for objects especially rapidly because these refer to concepts that are easy to perceive (McDonough et al., 2011; Parish-Morris et al., 2010). Soon children add verbs (*go, run, broke*), which require more complex understandings of relationships between objects and actions (Scott & Fisher, 2012). Children learning Chinese, Japanese, and Korean—languages in which nouns are often omitted from adult sentences, while verbs are stressed—acquire verbs much sooner (early in the second year) and more readily than their English-speaking age mates (Chan et al., 2011; Ma et al., 2009).

As young children acquire verbs, they also add modifiers (*red, round, sad*). Among those that are related in meaning, first they make general distinctions (*big–small*), then more specific ones (*tall–short, high–low, wide–narrow*) (Stevenson & Pollitt, 1987).

**Strategies for Word Learning.** Preschoolers figure out the meanings of new words by contrasting them with words they already know. How do they discover which concept each word picks out? One speculation is that early in vocabulary growth, children adopt a *mutual exclusivity bias*—the assumption that words refer to entirely separate (nonoverlapping) categories (Markman, 1992). Consistent with this idea, when 2-year-olds hear the labels for two distinct novel objects (for example, *clip* and *horn*), they assign each word correctly, to the whole object and not just a part of it (Waxman & Senghas, 1992).

Indeed, children's first several hundred nouns refer mostly to objects well-organized by shape. The process of learning nouns based on the perceptual property of shape heightens young children's attention to the distinctive shapes of other objects (Smith et al., 2002; Yoshida & Smith, 2003). This *shape bias* helps preschoolers master additional names of objects, and vocabulary accelerates.

Once the name of a whole object is familiar, on hearing a new name for the object, 2- and 3-year-olds set aside the mutual exclusivity assumption. For example, if the object (*bottle*) has a distinctively shaped part (*spout*), children readily apply the new label to it (Hansen & Markman, 2009). Still, mutual exclusivity and object shape cannot account for preschoolers' remarkably flexible responses when objects have more than one name. In these instances, children often call on other components of language.

According to one proposal, preschoolers discover many word meanings by observing how words are used in the structure of sentences (Gleitman et al., 2005; Naigles & Swenson, 2007). Consider an adult who says, “This is a *citron* one,” while showing the child a yellow car. Two- and 3-year-olds conclude that a new word used as an adjective for a familiar object (car) refers to a property of that object (Imai & Haryu, 2004). As children hear the word in various sentence structures (“That lemon is bright *citron*”), they refine its meaning and generalize it to other categories.

Young children also take advantage of rich social information that adults frequently provide, while drawing on their own expanding ability to infer others' intentions, desires, and perspectives. In one study, an adult performed an action on an object and then used a new label while looking back and forth between the child and the object, as if inviting the child to play. Two-year-olds concluded that the label referred to the action, not the object (Tomasello & Akhtar, 1995). By age 3, children can even use a speaker's recently expressed desire (“I really want to play with the *riff*”) to figure out the label belonging to one of two novel objects (Saylor & Troseth, 2006).

Adults also inform children directly about which of two or more words to use—by saying, for example, “You can call it a sea creature, but it's better to say *dolphin*.” Preschoolers' vocabularies grow more quickly when they have parents who provide such clarifying information (Callanan & Sabbagh, 2004).

Furthermore, to fill in for words they have not yet learned, children as young as age 3 coin new words using ones they already know—“plant-man” for a gardener, “crayoner” for a child using crayons. Preschoolers also extend language meanings through metaphors based on concrete sensory comparisons: “Clouds are pillows,” “Leaves are dancers.” Once vocabulary and general knowledge expand, children also appreciate nonsensory comparisons: “Friends are like magnets,” “Time flies by” (Keil, 1986; Özcaliskan, 2005). Metaphors permit young children to communicate in amazingly vivid and memorable ways.

**Explaining Vocabulary Development.** Children acquire vocabulary so efficiently and accurately that some theorists believe that they are innately biased to induce word meanings using certain principles, such as mutual exclusivity (Lidz, Gleitman, & Gleitman, 2004). But critics point out that a small set of built-in, fixed principles cannot account for the varied, flexible manner in which children master vocabulary (MacWhinney, 2015; Parish-Morris, Golinkoff, & Hirsh-Pasek, 2013). And many word-learning strategies cannot be innate because children acquiring different languages use different approaches to mastering the same meanings.

An alternative view is that vocabulary growth is governed by the same cognitive strategies that children apply to nonlinguistic information. According to one account, children draw on a *coalition* of cues—perceptual, social, and linguistic—which shift in importance with age (Golinkoff & Hirsh-Pasek, 2006, 2008). Infants rely solely on perceptual features. Toddlers and young preschoolers, while still sensitive to perceptual features (such as object shape and physical action), increasingly attend to social

LAURIE AND CHARLES/GETTY IMAGES

Young children rely on any useful information available to add to their vocabularies. As this child observes her father creating a sculpture, she attends to a variety of perceptual, social, and linguistic cues to grasp the meanings of unfamiliar words, such as *plaster, statue, base, form, sculpt, mold, and studio*.

cues—the speaker’s direction of gaze, gestures, and expressions of intention and desire (Hollich, Hirsh-Pasek, & Golinkoff, 2000; Pruden et al., 2006). And as language develops further, linguistic cues—sentence structure and intonation (stress, pitch, and loudness)—play larger roles.

Preschoolers are most successful at figuring out new word meanings when several kinds of information are available (Parish-Morris, Golinkoff, & Hirsh-Pasek, 2013). Researchers have just begun to study the multiple cues that children use for different kinds of words and how their combined strategies change with development.

## Grammar

Between ages 2 and 3, English-speaking children use simple sentences that follow a subject–verb–object word order. Children learning other languages adopt the word orders of the adult speech to which they are exposed.

**Basic Rules.** Toddlers’ greater looking times at scenes that match sentences they hear reveal that they comprehend the meaning of basic grammatical structures that they cannot yet produce, such as “Big Bird is tickling Cookie Monster” or “What did the ball hit?” (Seidl, Hollich, & Jusczyk, 2003). First use of grammatical rules, however, is piecemeal—limited to just a few

verbs. As children listen for familiar verbs in adults’ speech, they expand their own utterances containing those verbs, relying on adult speech as their model (Gathercole, Sebastián, & Soto, 1999). Sammy, for example, added the preposition *with* to the verb *open* (“You open with scissors”) but not to the word *hit* (“He hit me stick”).

To test preschoolers’ ability to generate novel sentences that conform to basic English grammar, researchers had them use a new verb in the subject–verb–object form after hearing it in a different construction, such as passive: “Ernie is getting *gorped* by the dog.” When children were asked what the dog was doing, the percentage who could respond “He’s *gorping* Ernie” rose steadily with age. But not until age 3½ to 4 could the majority of children apply the fundamental subject–verb–object structure broadly, to newly acquired verbs (Chan et al., 2010; Tomasello, 2006).

Once children form three-word sentences, they make small additions and changes to words that enable them to express meanings flexibly and efficiently. For example, they add *-ing* for ongoing actions (*playing*), add *-s* for plural (*cats*), use prepositions (*in* and *on*), and form various tenses of the verb *to be* (*is, are, were, has been, will*). English-speaking children master these grammatical markers in a regular sequence, starting with those that involve the simplest meanings and structures (Brown, 1973).

When preschoolers acquire these markers, they sometimes overextend the rules to words that are exceptions—a type of error called **overregularization**. “My toy car *breaked*” and “We each got two *foots*” are expressions that appear between ages 2 and 3 (Maratsos, 2000; Marcus, 1995).

**Complex Structures.** Gradually, preschoolers master more complex grammatical structures, although they do make mistakes. In first creating questions, 2- to 3-year-olds use many formulas: “Where’s *X*?” “Can I *X*?” (Dabrowska, 2000; Tomasello, 2003). Question asking remains variable for the next couple of years. An analysis of one child’s questions revealed that he inverted the subject and verb when asking certain questions (“What she will do?” “Why he can go?”) but not others. The correct expressions were the ones he heard most often in his mother’s speech (Rowland & Pine, 2000). And sometimes children produce errors in subject–verb agreement (“Where does the dogs play?”) and subject case (“Where can me sit?”) (Rowland, 2007).

Similarly, children have trouble with some passive sentences. When told, “The car is pushed by the truck,” young preschoolers often make a toy car push a truck. By age 4½, they understand such expressions, whether they contain familiar or novel verbs (Dittmar et al., 2014). But full mastery of the passive form is not complete until the end of middle childhood.

Nevertheless, preschoolers’ grasp of grammar is remarkable. By age 4 to 5, they form embedded sentences (“I think *he will come*”), tag questions (“Dad’s going to be home soon, *isn’t he?*”), and indirect objects (“He showed *his friend* the present”) (Zukowski, 2013). As the preschool years draw to a close, children use most of the grammatical constructions of their language competently.

**Explaining Grammatical Development.** Evidence that grammatical development is an extended process has raised questions about Chomsky's nativist theory (to review, see page 174 in Chapter 5). Some experts believe that grammar is a product of general cognitive development—children's tendency to search the environment for consistencies and patterns of all sorts. These *information-processing theorists* believe that children notice which words appear in the same positions in sentences and are combined in the same way with other words (Howell & Becker, 2013; MacWhinney, 2015; Tomasello, 2011). Over time, they group words into grammatical categories and use them appropriately in sentences.

Other theorists, while also focusing on how children process language, agree with the essence of Chomsky's theory—that the grammatical categories into which children group word meanings are innate, present at the outset (Pinker, 1999; Tien, 2013). Critics, however, point out that toddlers' two-word utterances do not reflect a flexible grasp of grammar and that preschoolers make many errors in their gradual mastery of grammar. In sum, controversy persists over whether a universal, built-in language acquisition device exists or whether children draw on general cognitive-processing procedures, devising unique strategies adapted to the specific language that they hear.

## Conversation

Besides acquiring vocabulary and grammar, children must learn to engage in effective and appropriate communication. This practical, social side of language is called **pragmatics**, and preschoolers make considerable headway in mastering it.

As early as age 2, children are skilled conversationalists. In face-to-face interaction, they take turns and respond appropriately to their partners' remarks. With age, the number of turns over which children can sustain interaction, ability to maintain a topic over time, and responsiveness to queries requesting clarification increase (Comeau, Genesee, & Mendelson, 2010; Snow et al., 1996). By age 3, children can infer a speaker's intention when the speaker expresses it indirectly. For example, most know that an adult who, in response to an offer of cereal, says, "We have no milk," is declining the cereal (Schulze, Grassmann, & Tomasello, 2013). These surprisingly advanced abilities probably grow out of early interactive experiences.

By age 4, children adjust their speech to fit the age, sex, and social status of their listeners. For example, in acting out roles with hand puppets, they use more commands when playing socially dominant and male roles (teacher, doctor, father) but speak more politely and use more indirect requests when playing less dominant and female roles (student, patient, mother) (Anderson, 2000).

Preschoolers' conversations appear less mature in highly demanding situations in which they cannot see their listeners' reactions or rely on typical conversational aids, such as gestures or objects to talk about. When asked in a phone conversation what he received for his birthday, one 3-year-old held up a new toy and said, "This!" But 3- to 6-year-olds give more specific

© LAURA DWIGHT PHOTOGRAPHY

These preschoolers likely use more assertive language when speaking for a male puppet than they would if speaking for a female puppet. In doing so, they reveal their early grasp of stereotypic features of social roles in their culture.

directions about how to solve a puzzle over the phone than in person, indicating that they realize that more verbal description is necessary on the phone (Cameron & Lee, 1997). Between ages 4 and 8, both conversing and giving directions over the phone improve greatly.

## Supporting Language Learning in Early Childhood

As in toddlerhood, conversational give-and-take with adults, either at home or in preschool, is consistently related to language progress (Hart & Risley, 1995; Huttenlocher et al., 2010). In addition, sensitive, caring adults use specific techniques that promote early language skills. When children use words incorrectly or communicate unclearly, they give helpful, explicit feedback: "I can't tell which ball you want. Do you mean the large red one?" But they do not overcorrect, especially when children make grammatical mistakes. Criticism discourages children from freely using language in ways that lead to new skills.

Instead, adults generally provide indirect feedback about grammar by using two strategies, often in combination: **recasts**—restructuring inaccurate speech into correct form, and **expansions**—elaborating on children's speech, increasing its complexity (Bohannon & Stanowicz, 1988; Chouinard & Clark, 2003). For example, if a child says, "I gotted new red shoes," the parent might respond, "Yes, you got a pair of new red shoes." In one study, after such corrective input, 2- to 4-year-olds often shifted to correct forms—improvements still evident several months later (Saxton, Backley, & Gallaway, 2005). However, the impact of such feedback has been challenged. The techniques are not used in all cultures and, in a few investigations, had no impact on children's grammar (Strapp & Federico, 2000; Valian, 1999). Rather than eliminating errors, perhaps expansions and recasts model grammatical alternatives and encourage children to experiment with them.

Do the findings just described remind you once again of Vygotsky's theory? In language, as in other aspects of cognitive development, parents and teachers gently prompt children to take the next step forward. Children strive to master language because they want to connect with other people. Adults, in turn, respond to children's desire to become competent speakers by listening attentively, elaborating on what children say, modeling correct usage, and stimulating children to talk further. In the next chapter, we will see that this combination of warmth and encouragement of mature behavior is at the heart of early childhood emotional and social development as well.

## Ask yourself

**CONNECT** Explain how children's strategies for word learning support the interactionist perspective on language development, described on pages 174–175 in Chapter 5.

**APPLY** Sammy's mother explained to him that the family would take a vacation in Miami. The next morning, Sammy announced, "I gotted my bags packed. When are we going to Your-ami?" What explains Sammy's errors?

## Summary / chapter 7

### PHYSICAL DEVELOPMENT

#### A Changing Body and Brain

(p. 216)

##### 7.1 Describe body growth and brain development during early childhood.

- Gains in body size taper off in early childhood as children become longer and leaner. New epiphyses emerge in the skeleton, and by the end of the preschool years, children start to lose their primary teeth.
- Neural fibers in the brain continue to form synapses and to myelinate, followed by synaptic pruning and increasing localization of cognitive capacities in regions of the cerebral cortex. Pre-frontal-cortical areas devoted to various aspects of executive function develop rapidly. The left cerebral hemisphere is especially active, supporting preschoolers' expanding language skills and improved executive function.
- Hand preference, reflecting an individual's **dominant cerebral hemisphere**, strengthens during early childhood. Research on handedness supports the joint contribution of nature and nurture to brain lateralization.
- Fibers linking the **cerebellum** to the cerebral cortex grow and myelinate, enhancing motor coordination and thinking. The **reticular formation**, responsible for alertness and consciousness; the **hippocampus**, which plays a vital role in memory and spatial understanding; the **amygdala**, which plays a central role in processing novelty and emotional information; and the **corpus callosum**, connecting the two cerebral hemispheres, also form synapses and myelinate.

#### Influences on Physical Growth and Health (p. 219)

##### 7.2 Describe the effects of heredity, nutrition, and infectious disease on physical growth and health in early childhood.

- Heredity controls production and release of two hormones by the **pituitary gland: growth hormone (GH)**, which is necessary for development of almost all body tissues, and **thyroid-stimulating hormone (TSH)**, which affects brain development and body size.
- As growth rate slows, preschoolers' appetites decline, and they often become wary of new foods. Repeated, unpressured exposure to new foods promotes healthy, varied eating.

© ADAM HESTER/CORBIS

- Dietary deficiencies, especially in protein, vitamins, and minerals, are associated with stunted physical growth, attention and memory difficulties, and academic and behavior problems. Disease also contributes to malnutrition, especially when intestinal infections cause persistent diarrhea.
- Immunization rates are lower in the United States than in other industrialized nations because many low-income children lack access to health care. Parental stress and misconceptions about vaccine safety also contribute.

##### 7.3 What factors increase the risk of unintentional injuries, and how can childhood injuries be prevented?

- Unintentional injuries are the leading cause of childhood mortality in industrialized nations. Victims are more likely to be boys; to be temperamentally inattentive, overactive, irritable, defiant, and aggressive; and to be growing up in poverty-stricken homes and neighborhoods.
- Effective injury prevention includes passing laws that promote child safety; creating safer home, travel, and play environments; improving public education; changing parent and child behaviors; and providing social supports to ease parental stress.

#### Motor Development (p. 222)

##### 7.4 Cite major milestones of gross- and fine-motor development, along with factors that affect motor progress, in early childhood.

- As the child's center of gravity shifts toward the trunk, balance improves, paving the way for new gross-motor achievements. Preschoolers run, jump, hop, gallop and eventually skip, throw, and catch, and generally become better coordinated.
- Improved control of the hands and fingers leads to dramatic gains in fine-motor skills. Preschoolers gradually become self-sufficient at dressing and feeding.
- By age 3, children's scribbles become pictures. With age, drawings increase in complexity and realism, influenced by gains in children's cognitive and fine-motor capacities and by their culture's artistic traditions. Cognitive advances and exposure to written materials contribute to progress in accurately printing alphabet letters.

- Body build and opportunity for physical play affect motor development. Sex differences favoring boys in force and power and girls in balance and fine movements are partly genetic, but environmental pressures exaggerate them. Children master the motor skills of early childhood through informal play experiences.

## COGNITIVE DEVELOPMENT

### Piaget's Theory: The Preoperational Stage (p. 227)

**7.5 Describe advances in mental representation, and limitations of thinking, during the preoperational stage.**

- Rapid advances in mental representation mark the beginning of Piaget's **preoperational stage**. Make-believe, which supports many aspects of development, becomes increasingly complex, evolving into **sociodramatic play** with peers. **Dual representation** improves rapidly over the third year as children realize that models, drawings, and simple maps correspond to circumstances in the real world.
- Preoperational children's cognitive limitations include **egocentrism**, **centration**, a focus on one aspect of a situation and on perceptual appearances, and **irreversibility**. As a result, they fail **conservation** and **hierarchical classification** tasks.

© ELLEN B. SENISI

**7.6 What does follow-up research imply about the accuracy of Piaget's preoperational stage?**

- When young children are given simplified tasks relevant to their everyday lives, their performance appears more mature than Piaget assumed. Preschoolers recognize others' perspectives, distinguish animate from inanimate objects, have flexible and appropriate notions of magic, reason by analogy about physical transformations, understand cause-and-effect relationships, and organize knowledge into hierarchical categories.

- Evidence that operational thinking develops gradually over the preschool years challenges Piaget's stage concept. Some theorists propose a more flexible view of stages.

**7.7 What educational principles can be derived from Piaget's theory?**

- A Piagetian classroom promotes discovery learning, sensitivity to children's readiness to learn, and acceptance of individual differences.

### Vygotsky's Sociocultural Theory

(p. 234)

**7.8 Describe Vygotsky's perspective on the social origins and significance of children's private speech.**

- Unlike Piaget, Vygotsky regarded language as the foundation for all higher cognitive processes. According to Vygotsky, **private speech**, or language used for self-guidance, emerges out of social communication as adults and more skilled peers help children master appropriately challenging tasks. Private speech is eventually internalized as silent, inner speech.

- **Scaffolding**—adjusting teaching support to fit children's current needs and suggesting strategies—promotes gains in children's thinking.

**7.9 Describe applications of Vygotsky's theory to education, and evaluate his major ideas.**

- A Vygotskian classroom emphasizes assisted discovery—verbal guidance from teachers and peer collaboration. Make-believe play is a vital zone of proximal development in early childhood.
- **Guided participation**, a broader concept than scaffolding, recognizes situational and cultural variations in shared endeavors between more expert and less expert participants.

### Information Processing (p. 236)

**7.10 How do executive function and memory change during early childhood?**

- Executive function improves markedly over the preschool years. Children gain in inhibition, ability to flexibly shift their focus of attention, and working-memory capacity—executive function components that are closely interconnected and that contribute vitally to academic and social skills. Older preschoolers also gain in planning, a complex executive function activity.

© LAURA DWIGHT PHOTOGRAPHY

- Parental scaffolding supports preschoolers' executive function skills. Poverty exerts a negative impact, in part through maladaptive parenting and chronic stress.
- Young children's recognition memory is remarkably accurate, but their recall of listlike information is poor because they use **memory strategies** less effectively than older children.
- **Episodic memory**—memory for everyday experiences—improves greatly in early childhood. Like adults, preschoolers remember recurring events as **scripts**, which become increasingly elaborate with age.
- As cognitive and conversational skills improve, children's autobiographical memories become more organized and detailed, especially when adults use an elaborative style in talking about the past.

**7.11 Describe the young child's theory of mind.**

- Preschoolers begin to construct a theory of mind, evidence of their capacity for **metacognition**. Between ages 4 and 6, explicit false-belief understanding becomes more secure, enhancing children's capacity to reflect on their own and others' thoughts and emotions. Language, executive function, and social experiences contribute.
- Preschoolers regard the mind as a passive container of information rather than as an active, constructive agent.

**7.12 Summarize children's literacy and mathematical knowledge during early childhood.**

- Preschoolers' **emergent literacy** reveals that they revise their ideas about the meaning of print as their cognitive capacities improve, as they encounter writing in many contexts, and as adults help them with written communication. **Phonological awareness** is a strong predictor of emergent literacy knowledge and later spelling and reading achievement. Informal literacy experiences, including adult-child interactive storybook reading, foster literacy development.

- Toddlers display a beginning grasp of **ordinality**. By age 3½ to 4, preschoolers understand **cardinality** and use counting to solve arithmetic problems, eventually arriving at the most efficient, accurate approach. Adults promote children's mathematical knowledge by providing many occasions for counting, comparing quantities, and talking about number concepts.

### Individual Differences in Mental Development (p. 245)

#### 7.13 Describe early childhood intelligence tests and the impact of home, preschool and kindergarten programs, child care, and educational media on mental development.

- Intelligence tests for young children sample a range of verbal and nonverbal skills. By age 6 to 7, scores are good predictors of later IQ and academic achievement. Children growing up in warm, stimulating homes with parents who make reasonable demands for mature behavior develop well intellectually.
- Preschool and kindergarten programs include both **child-centered programs**, in which much learning occurs through play, and **academic programs**, in which teachers structure children's learning, often using repetition and drill. Emphasizing formal academic training undermines young children's motivation and negatively influences later achievement.

- **Project Head Start** is the most extensive U.S. federally funded preschool program for low-income children. High-quality preschool intervention results in immediate IQ and achievement gains and long-term improvements in school adjustment.
- Enriching Head Start classrooms with Head Start REDI yields higher year-end language, literacy, and social skills. Good child care enhances cognitive, language, and social development, especially for low-SES children.

© LAURA DWIGHT PHOTOGRAPHY

- Children gain in diverse cognitive skills from educational television and computer software. TV programs with slow-paced action and easy-to-follow story lines foster executive function, vocabulary and reading skills, and elaborate make-believe play. Computer programs that introduce children to programming skills promote problem solving and metacognition. But heavy exposure to prime-time TV and cartoons is associated with poorer academic skills.

### Language Development (p. 249)

#### 7.14 Trace the development of vocabulary, grammar, and conversational skills in early childhood.

- Supported by **fast-mapping**, preschoolers' vocabularies increase dramatically. Initially, they rely heavily on the perceptual cue of object shape to expand their vocabulary. With age, they increasingly draw on social and linguistic cues.
- Between ages 2 and 3, children adopt the basic word order of their language. As preschoolers gradually master grammatical rules, they sometimes overextend them in a type of error called **overregularization**. By the end of early childhood, children have acquired complex grammatical forms.
- **Pragmatics** is the practical, social side of language. Two-year-olds are already skilled conversationalists in face-to-face interaction. By age 4, children adapt their speech to their listener's age, sex, and social status.

#### 7.15 Cite factors that support language learning in early childhood.

- Conversational give-and-take with adults fosters language progress. Adults provide explicit feedback on the clarity of children's language and indirect feedback about grammar through **recasts and expansions**.

## Emotional and Social Development in Early Childhood

During the preschool years, children make great strides in understanding the thoughts and feelings of others, and they build on these skills as they form first friendships—special relationships marked by attachment and common interests.

Styles of Child Rearing • What Makes Authoritative Child Rearing Effective? • Cultural Variations • Child Maltreatment

As the children in Leslie's classroom moved through the preschool years, their personalities took on clearer definition. By age 3, they voiced firm likes and dislikes as well as new ideas about themselves. "Stop bothering me," Sammy said to Mark, who had reached for Sammy's beanbag as Sammy aimed it toward the mouth of a large clown face. "See, I'm great at this game," Sammy announced with confidence, an attitude that kept him trying, even though he missed most of the throws.

The children's conversations also revealed early notions about morality. Often they combined statements about right and wrong with forceful attempts to defend their own desires. "You're 'posed to share," stated Mark, grabbing the beanbag out of Sammy's hand.

"I was here first! Gimme it back," demanded Sammy, pushing Mark. The two boys struggled until Leslie intervened, provided an extra set of beanbags, and showed them how they could both play.

As the interaction between Sammy and Mark reveals, preschoolers quickly become complex social beings. Young children argue, grab, and push, but cooperative exchanges are far more frequent. Between ages 2 and 6, first friendships form, in which children converse, act out complementary roles, and learn that their own desires for companionship and toys are best met when they consider others' needs and interests.

The children's developing understanding of their social world was especially apparent in their growing attention to the dividing line between male and female. While Priti and Karen cared for a sick baby doll in the housekeeping area, Sammy, Vance, and Mark transformed the block corner into a busy intersection. "Green light, go!" shouted police officer Sammy as Vance and Mark pushed large wooden cars and trucks across the floor. Already, the children preferred peers of their own gender, and their play themes mirrored their culture's gender stereotypes.

This chapter is devoted to the many facets of early childhood emotional and social development. We begin with Erik Erikson's theory, which provides an overview of personality change in the preschool years. Then we consider children's concepts of themselves, their insights into their social and moral worlds, their gender typing, and their increasing ability to manage their emotional and social behaviors. Finally, we ask, What is effective child rearing? And we discuss the complex conditions that support good parenting or lead it to break down, including the serious and widespread problems of child abuse and neglect. ●

© LAURA DWIGHT PHOTOGRAPHY

## Erikson's Theory: Initiative versus Guilt

**8.1** What personality changes take place during Erikson's stage of initiative versus guilt?

Erikson (1950) described early childhood as a period of “vigorous unfolding.” Once children have a sense of autonomy, they become less contrary than they were as toddlers. Their energies are freed for tackling the psychological conflict of the preschool years: **initiative versus guilt**. As the word *initiative* suggests, young children have a new sense of purposefulness. They are eager to tackle new tasks, join in activities with peers, and discover what they can do with the help of adults. They also make strides in conscience development.

Erikson regarded play as a means through which young children learn about themselves and their social world. Play permits preschoolers to try new skills with little risk of criticism and failure. It also creates a small social organization of children who must cooperate to achieve common goals. Around the world, children act out family scenes and highly visible occupations—police officer, doctor, and nurse in Western societies, rabbit

hunter and potter among the Hopi Indians, hut builder and spear maker among the Baka of West Africa (Gaskins, 2013).

Recall that Erikson's theory builds on Freud's psychosexual stages (see Chapter 1, page 15). In Freud's Oedipus and Electra conflicts, to avoid punishment and maintain parents' affection, children form a *superego*, or conscience, by *identifying* with the same-sex parent. As a result, they adopt the moral and gender-role standards of their society. For Erikson, the negative outcome of early childhood is an overly strict superego that causes children to feel too much guilt because they have been threatened, criticized, and punished excessively by adults. When this happens, preschoolers' exuberant play and bold efforts to master new tasks break down.

Although Freud's ideas are no longer accepted as satisfactory explanations of conscience development, Erikson's image of initiative captures the diverse changes in young children's emotional and social lives. Early childhood is, indeed, a time when children develop a confident self-image, more effective control over their emotions, new social skills, the foundations of morality, and a clear sense of themselves as boy or girl.

## Self-Understanding

**8.2** Describe the development of self-concept and self-esteem in early childhood.

The development of language enables young children to talk about their own subjective experience of being. In Chapter 7, we noted that young children acquire a vocabulary for talking about their inner mental lives and refine their understanding of mental states. As self-awareness strengthens, preschoolers focus more intently on qualities that make the self unique. They begin to develop a **self-concept**, the set of attributes, abilities, attitudes, and values that an individual believes defines who he or she is.

## Foundations of Self-Concept

Ask a 3- to 5-year-old to tell you about himself, and you are likely to hear something like this: “I'm Tommy. I'm 4 years old. I can wash my hair all by myself. I have a new Lego set, and I made this big, big tower.” Preschoolers' self-concepts consist largely of observable characteristics, such as their name, physical appearance, possessions, and everyday behaviors (Harter, 2012).

By age 3½, children also describe themselves in terms of typical emotions and attitudes (“I'm happy when I play with my friends”; “I don't like scary TV programs”; “I usually do what Mommy says”), suggesting a beginning understanding of their unique psychological characteristics (Eder & Mangelsdorf, 1997). And by age 5, children's degree of agreement with such statements coincides with maternal reports of their personality traits, indicating that older preschoolers have a sense of their own

A Guatemalan 3-year-old pretends to shell corn. By acting out family scenes and highly visible occupations, young children around the world develop a sense of initiative, gaining insight into what they can do and become in their culture.

## Cultural Influences

### Cultural Variations in Personal Storytelling: Implications for Early Self-Concept

Preschoolers of many cultural backgrounds participate in personal storytelling with their parents. Striking cultural differences exist in parents' selection and interpretation of events in these narratives, affecting the way children view themselves.

In one study, researchers spent hundreds of hours over a two-year period studying the storytelling practices of six middle-SES Irish-American families in Chicago and six middle-SES Chinese families in Taiwan. From extensive videotapes of adults' conversations with the children from ages 2½ to 4, the investigators identified personal stories and coded them for content, quality of their endings, and evaluation of the child (Miller, Fung, & Mintz, 1996; Miller et al., 1997, 2012b).

Parents in both cultures discussed pleasurable holidays and family excursions in similar ways and with similar frequency. But five times more often than the Irish-American parents, the Chinese parents told long stories about their preschooler's previous misdeeds—using impolite language, writing on the wall, or playing in an overly rowdy way. These narratives, often sparked by a current misdeed, were conveyed with warmth and caring, stressed the impact of misbehavior on others

(“You made Mama lose face”), and often ended with direct teaching of proper behavior (“Saying dirty words is not good”). By contrast, in the few instances in which Irish-American stories referred to transgressions, parents downplayed their seriousness, attributing them to the child's spunk and assertiveness.

Early narratives about the child launch preschoolers' self-concepts on culturally distinct paths (Miller, 2014). Influenced by Confucian traditions of strict discipline and social obligations, Chinese parents integrated these values into their stories, affirming the importance of not disgracing the family and explicitly conveying expectations for improvement in the story's conclusion. Although Irish-American parents disciplined their children, they rarely dwelt on misdeeds in storytelling. Rather, they cast the child's shortcomings in a positive light, perhaps to promote self-esteem.

Whereas most Americans believe that favorable self-esteem is crucial for healthy development, Chinese adults generally see it as unimportant or even negative—as impeding the child's willingness to listen and be corrected (Miller et al., 2002). Consistent with

RONNIE KAUFMAN/LARRY HIRSHOWITZ/BLEND IMAGES/GETTY IMAGES

A Chinese mother speaks gently to her child about proper behavior. Chinese parents often tell preschoolers stories that point out the negative impact on others of the child's misdeeds. The Chinese child's self-concept, in turn, emphasizes social obligations.

this view, the Chinese parents did little to cultivate their child's individuality. Instead, they used storytelling to guide the child toward responsible behavior. Hence, the Chinese child's self-image emphasizes obligations to others, whereas the American child's is more autonomous.

timidity, agreeableness, and positive or negative affect (Brown et al., 2008). But most preschoolers do not yet say, “I'm helpful” or “I'm shy.” Direct references to personality traits must wait for greater cognitive maturity.

A warm, sensitive parent-child relationship fosters a more positive, coherent early self-concept. Recall from Chapter 7 that securely attached preschoolers participate in more elaborative parent-child conversations about personally experienced events, which help them understand themselves (see page 242). Elaborative reminiscing that focuses on children's internal states—thoughts, feelings, and subjective experiences—plays an especially important role in early self-concept development. For example, when parents reminisce with preschoolers about times they successfully resolved upsetting feelings, 4- and 5-year-olds describe their emotional tendencies more favorably (“I'm not

scared—not me!”) (Goodvin & Romdall, 2013). By emphasizing the personal meaning of past events, conversations about internal states facilitate self-knowledge.

As early as age 2, parents use narratives of past events to impart rules, standards for behavior, and evaluative information about the child: “You added the milk when we made the mashed potatoes. That's a very important job!” (Nelson, 2003). As the Cultural Influences box above reveals, these self-evaluative narratives are a major means through which caregivers imbue the young child's self-concept with cultural values.

As they talk about personally significant events and as their cognitive skills advance, preschoolers gradually come to view themselves as persisting over time—a change evident in their improved ability to anticipate their own future states and needs. When asked to select from three items (a raincoat, money, a

blanket) the one they need to bring with them to a future event (walking next to a waterfall), children's performance—along with future-state justifications (“I’m gonna get wet”)—increased sharply between ages 3 and 4 (Atance & Meltzoff, 2005). And by age 5, children better understand that their future preferences are likely to differ from their current ones. Most realize that when they grow up, they will prefer reading newspapers to reading picture books and drinking coffee to drinking grape juice (Bélanger et al., 2014). By the end of the preschool years, children can set aside their current state of mind and take a future perspective.

## Emergence of Self-Esteem

Another aspect of self-concept emerges in early childhood: **self-esteem**, the judgments we make about our own worth and the feelings associated with those judgments. These evaluations are among the most important aspects of self-development because they affect our emotional experiences, future behavior, and long-term psychological adjustment.

By age 4, preschoolers have several self-judgments—for example, about learning things in school, making friends, getting along with parents, and treating others kindly (Marsh, Ellis, & Craven, 2002). But they lack the cognitive maturity to combine these evaluations into a global sense of self-esteem. Also, because they have difficulty distinguishing between their desired and their actual competence, they usually rate their own ability as extremely high and underestimate task difficulty, as Sammy did when he asserted, despite his many misses, that he was great at beanbag throwing (Harter, 2012).

© LAURA DWIGHT PHOTOGRAPHY

This preschooler confidently prepares to slide down the pole of a playground jungle gym. Her high self-esteem contributes greatly to her initiative in mastering new skills.

High self-esteem contributes greatly to preschoolers' initiative during a period in which they must master many new skills. By age 3, children whose parents patiently encourage while offering information about how to succeed are enthusiastic and highly motivated. In contrast, children whose parents criticize their worth and performance give up easily when faced with challenges and express shame and despondency after failing (Kelley, Brownell, & Campbell, 2000). Adults can avoid promoting these self-defeating reactions by adjusting their expectations to children's capacities, scaffolding children's attempts at difficult tasks (see Chapter 7, page 235), and pointing out effort and improvement in children's behavior.

## Emotional Development

**8.3** Identify changes in understanding and expressing emotion during early childhood, citing factors that influence those changes.

Gains in representation, language, and self-concept support emotional development in early childhood. Between ages 2 and 6, children make strides in emotional abilities that, collectively, researchers refer to as *emotional competence* (Denham et al., 2011). First, preschoolers gain in emotional understanding, becoming better able to talk about feelings and to respond appropriately to others' emotional signals. Second, they become better at emotional self-regulation—in particular, at coping with intense negative emotion. Finally, preschoolers more often experience *self-conscious emotions* and *empathy*, which contribute to their developing sense of morality.

Parenting strongly influences preschoolers' emotional competence. Emotional competence, in turn, is vital for successful peer relationships and overall mental health.

## Understanding Emotion

Early in the preschool years, children refer to causes, consequences, and behavioral signs of emotion (Thompson, Winer, & Goodvin, 2011). Over time, their understanding becomes more accurate and complex.

By age 4 to 5, children correctly judge the causes of many basic emotions (“He’s happy because he’s swinging very high”; “He’s sad because he misses his mother”). Preschoolers' explanations tend to emphasize external factors over internal states, a balance that changes with age (Rieffe, Terwogt, & Cowan, 2005). In Chapter 7, we saw that after age 4, children appreciate that both desires and beliefs motivate behavior. Once these understandings are secure, children's grasp of how internal factors can trigger emotion expands.

Preschoolers are good at inferring how others are feeling based on their behavior. For example, they can tell that a child who jumps up and down and claps his hands is probably happy and that a child who is tearful and withdrawn is sad (Widen & Russell, 2011). And they are beginning to realize that thinking

and feeling are interconnected—that focusing on negative thoughts (“I broke my arm, so now I have to wear this itchy cast that makes it hard to play”) is likely to make a person feel worse, but thinking positively (“Now I have a cool cast my friends can write their names on!”) can help a person feel better (Bamford & Lagattuta, 2012). Furthermore, preschoolers come up with effective ways to relieve others’ negative emotions, such as hugging to reduce sadness (Fabes et al., 1988). Overall, preschoolers have an impressive ability to interpret, predict, and change others’ feelings.

At the same time, preschoolers have difficulty interpreting situations that offer conflicting cues about how a person is feeling. When asked what might be happening in a picture of a happy-faced child with a broken bicycle, 4- and 5-year-olds tended to rely only on the emotional expression: “He’s happy because he likes to ride his bike.” Older children more often reconciled the two cues: “He’s happy because his father promised to help fix his broken bike” (Gnepp, 1983; Hoffner & Badzinski, 1989). This capacity requires improved executive function—retaining in working memory two conflicting sources of information while drawing on one’s knowledge base to integrate them.

The more parents label and explain emotions and express warmth when conversing with preschoolers, the more “emotion words” children use and the better developed their emotion understanding (Fivush & Haden, 2005; Laible & Song, 2006). Discussions of negative experiences or disagreements are particularly helpful because they evoke more elaborative dialogues that include validation of children’s feelings (Laible, 2011). In one study, mothers who explained emotions and negotiated and compromised during conflicts with their 2½-year-olds had children who, at age 3, were advanced in emotional understanding and used similar strategies to resolve disagreements (Laible & Thompson, 2002). Such dialogues seem to help children reflect

on the causes and consequences of emotion while modeling mature communication skills.

Knowledge about emotion helps children in their efforts to get along with others. As early as 3 to 5 years of age, it is related to friendly, considerate behavior, constructive responses to disputes with agemates, and perspective-taking ability (Garner & Estep, 2001; Hughes & Ensor, 2010; O’Brien et al., 2011). And as children learn about emotion from interacting with adults, they engage in more emotion talk with agemates and siblings. Preschoolers who refer to feelings when interacting with playmates are better liked by their peers (Fabes et al., 2001). Children seem to recognize that acknowledging others’ emotions and explaining their own enhance the quality of relationships.

## Emotional Self-Regulation

Language, along with preschoolers’ growing understanding of the causes and consequences of emotion, contributes to gains in *emotional self-regulation* (Thompson, 2015). By age 3 to 4, children verbalize a variety of strategies for alleviating negative emotion that they tailor to specific situations (Davis et al., 2010; Dennis & Kelemen, 2009). For example, they know they can restrict sensory input (cover their eyes or ears to block out a scary sight or sound), talk to themselves (“Mommy said she’ll be back soon”), change their goals (decide that they don’t want to play anyway after being excluded from a game), or repair the situation (“stop fighting and share” to resolve a conflict with a peer). The effectiveness of preschoolers’ recommended strategies improves with age.

As children use these strategies, emotional outbursts decline. Gains in executive function—in particular, inhibition, flexible shifting of attention, and manipulating information in working memory—contribute greatly to managing emotion in early childhood. Three-year-olds who can distract themselves when upset and focus on how to handle their feelings tend to become cooperative school-age children with few problem behaviors (Gilliom et al., 2002).

By watching parents manage emotion, children learn strategies for regulating their own. Parents who are in tune with their own emotional experiences tend to be supportive with their preschoolers, offering suggestions and explanations of emotion-regulation strategies that strengthen children’s capacity to handle stress (Meyer et al., 2014; Morris et al., 2011). In contrast, when parents rarely express positive emotion, dismiss children’s feelings as unimportant, and fail to control their own anger, children’s emotion management and psychological adjustment suffer (Hill et al., 2006; Thompson & Meyer, 2007).

Adult–child conversations that prepare children for difficult experiences by discussing what to expect and ways to handle anxiety also foster emotional self-regulation (Thompson & Goodman, 2010). Nevertheless, preschoolers’ vivid imaginations and incomplete grasp of the distinction between fantasy and reality make fears common in early childhood. See Applying What We Know on page 262 for ways to help young children manage fears.

Warm, elaborative conversations in which parents label and explain emotions enhance preschoolers’ emotional understanding.

## Applying what we Know

### Helping Children Manage Common Fears of Early Childhood

FEAR	SUGGESTION
Monsters, ghosts, and darkness	Reduce exposure to frightening stories and TV programs until the child is better able to understand that fantastical beings are not real. “Search” the child’s room for monsters, showing him that none are there. Use a night-light, sit by the child’s bed until he falls asleep, and tuck in a favorite toy for protection.
Preschool or child care	If the child resists going to preschool but seems content once there, the fear is probably separation. Provide a sense of warmth and caring while gently encouraging independence. If the child fears being at preschool, find out why—the teacher, the children, or a crowded, noisy environment. Provide support by accompanying the child and gradually lessening the amount of time you stay.
Animals	Do not force the child to approach a dog, cat, or other animal that arouses fear. Let the child move at her own pace. Demonstrate how to hold and pet the animal, showing that when treated gently, the animal is friendly. If the child is larger than the animal, emphasize this: “You’re so big. That kitty is probably afraid of <i>you!</i> ”
Intense fears	If a child’s fear is intense, persists for a long time, interferes with daily activities, and cannot be reduced in any of the ways just suggested, it has reached the level of a <i>phobia</i> . Sometimes phobias are linked to family problems and require counseling. Other phobias diminish without treatment as the child’s emotional self-regulation improves.

## Self-Conscious Emotions

One morning in Leslie’s classroom, a group of children crowded around for a bread-baking activity. Leslie asked them to wait patiently while she got a baking pan. But Sammy reached over to feel the dough, and the bowl tumbled off the table. When Leslie returned, Sammy looked at her, then covered his eyes with his hands and said, “I did something bad.” He felt ashamed and guilty.

As their self-concepts develop, preschoolers become increasingly sensitive to praise and blame or to the possibility of such feedback. They more often experience *self-conscious emotions*—feelings that involve injury to or enhancement of their sense of self (see Chapter 6). By age 3, self-conscious emotions are clearly linked to self-evaluation (Lagattuta & Thompson, 2007; Lewis, 1995). But because preschoolers are still developing standards of excellence and conduct, they depend on the messages of parents, teachers, and others who matter to them to know *when* to feel proud, ashamed, or guilty, often viewing adult expectations as obligatory rules (“Dad said you’re ’posed to take turns”) (Thompson, Meyer, & McGinley, 2006).

When parents repeatedly comment on the worth of the child and her performance (“That’s a bad job! I thought you were a good girl!”), children experience self-conscious emotions intensely—more shame after failure, more pride after success. In contrast, when parents focus on how to improve performance (“You did it this way; now try doing it that way”), they induce moderate, more adaptive levels of shame and pride and greater persistence on difficult tasks (Kelley, Brownell, & Campbell, 2000; Lewis, 1998).

Among Western children, intense shame is associated with feelings of personal inadequacy (“I’m stupid”; “I’m a terrible person”) and with maladjustment—withdrawal and depression

as well as intense anger and aggression toward those who participated in the shame-evoking situation (Muris & Meesters, 2014). In contrast, guilt—when it occurs in appropriate circumstances and is neither excessive nor accompanied by shame—is related to good adjustment. Guilt helps children resist harmful impulses, and it motivates a misbehaving child to repair the damage and behave more considerately (Mascolo & Fischer, 2007; Tangney, Stuewig, & Mashek, 2007). But overwhelming guilt—involving such high emotional distress that the child cannot make amends—is linked to depressive symptoms as early as age 3 (Luby et al., 2009).

Finally, the consequences of shame for children’s adjustment may vary across cultures. As illustrated in the Cultural Influences box on page 259, people in Asian societies, who tend to define themselves in relation to their social group, view shame as an adaptive reminder of an interdependent self and of the importance of others’ judgments (Friedlmeier, Corapci, & Cole, 2011).

## Empathy and Sympathy

*Empathy* is another emotional capacity that becomes more common in early childhood. It serves as a motivator of **prosocial, or altruistic, behavior**—actions that benefit another person without any expected reward for the self (Eisenberg, Spinrad, & Knafo-Noam, 2015). Compared with toddlers, preschoolers rely more on words to communicate empathic feelings, a change that indicates a more reflective level of empathy. When a 4-year-old received a Christmas gift that she hadn’t included on her list for Santa, she assumed it belonged to another little girl and pleaded with her parents, “We’ve got to give it back—Santa’s made a big mistake. I think the girl’s crying ’cause she didn’t get her present!”

Yet for some children, empathizing—*feeling with* an upset adult or peer and responding emotionally in a similar way—does not yield acts of kindness and helpfulness but, instead, escalates into personal distress. In trying to reduce these negative feelings, the child focuses on his own anxiety rather than on the person in need. As a result, empathy does not lead to **sympathy**—feelings of concern or sorrow for another’s plight.

Temperament plays a role in whether empathy prompts sympathetic, prosocial behavior or a personally distressed, self-focused response. Children who are sociable, assertive, and good at regulating emotion are more likely to help, share, and comfort others in distress. But poor emotion regulators less often display sympathetic concern and prosocial behavior (Eisenberg, Spinrad, & Knafo-Noam, 2015; Valiente et al., 2004). When faced with someone in need, they react with behavioral and physiological distress—frowning, lip biting, thumb sucking, comfort seeking, a rise in heart rate, and a sharp increase in EEG brain-wave activity in the right cerebral hemisphere, which houses negative emotion—indications that they are overwhelmed by their feelings (Liew et al., 2010; Pickens, Field, & Nawrocki, 2001).

Preschoolers’ empathic concern strengthens in the context of a secure parent–child attachment relationship (Murphy & Laible, 2013). When parents are warm and sensitive and respond to their preschoolers’ feelings with empathy and sympathy, children react with concern to others’ distress—a response that persists into adolescence and early adulthood (Michalik et al., 2007; Newton et al., 2014; Taylor et al., 2013). Besides modeling empathy and sympathy, parents can teach children the importance of kindness and can intervene when they display inappropriate emotion—strategies that predict high levels of sympathetic responding (Eisenberg, 2003).

In contrast, angry, punitive parenting can disrupt the development of empathy and sympathy at an early age (Knafo &

Plomin, 2006). Physically abused preschoolers, who experience negative parenting to an extreme, rarely express concern at a peer’s unhappiness but, rather, are likely to withdraw or react with verbal and physical attacks (Anthonysamy & Zimmer-Gembeck, 2007). Their behavior resembles their parents’ insensitive responding to others’ suffering.

## Peer Relations

**8.4** Describe peer sociability and friendship in early childhood, along with cultural and parental influences on early peer relations.

As children become increasingly self-aware and better at communicating and understanding others’ thoughts and feelings, their skill at interacting with peers improves rapidly. Peers provide young children with learning experiences they can get in no other way. Because peers interact on an equal footing, children must keep a conversation going, cooperate, and set goals in play. With peers, children form friendships—special relationships marked by attachment and common interests. Let’s look at how peer interaction changes over the preschool years.

### Advances in Peer Sociability

Mildred Parten (1932), one of the first to study peer sociability among 2- to 5-year-olds, noticed a dramatic rise with age in joint, interactive play. She concluded that social development proceeds in a three-step sequence. It begins with **nonsocial activity**—unoccupied, onlooker behavior and solitary play. Then it shifts to **parallel play**, in which a child plays near other children with similar materials but does not try to influence their behavior. At the highest level are two forms of true social interaction. In **associative play**, children engage in separate activities but exchange toys and comment on one another’s behavior. Finally, in **cooperative play**, a more advanced type of interaction, children orient toward a common goal, such as acting out a make-believe theme.

**Follow-Up Research on Peer Sociability.** Longitudinal evidence indicates that these play forms emerge in the order suggested by Parten but that later-appearing ones do not replace earlier ones in a developmental sequence (Rubin, Bukowski, & Parker, 2006). Rather, all types coexist in early childhood.

During classroom free-play periods, preschoolers often transition from onlooker to parallel to cooperative play and back again (Robinson et al., 2003). They seem to use parallel play as a way station—a respite from the demands of complex social interaction and a crossroad to new activities. And although nonsocial activity declines with age, it is still the most frequent form among 3- to 4-year-olds and accounts for one-third of kindergartners’ free-play time. Also, both solitary and parallel play remain fairly stable from 3 to 6 years, accounting for as much of the child’s play as cooperative interaction (Rubin, Fein, & Vandenberg, 1983).

Four-year-olds (left) engage in parallel play. Cooperative play (right) develops later than parallel play, but preschool children continue to move back and forth between the two types of sociability, using parallel play as a respite from the complex demands of cooperation.

We now understand that the *type*, not the amount, of solitary and parallel play changes during early childhood. In studies in Taiwan and the United States, researchers rated the *cognitive maturity* of nonsocial, parallel, and cooperative play, using the categories shown in Table 8.1. Within each of Parten's play types, older children displayed more cognitively mature behavior than younger children (Pan, 1994; Rubin, Watson, & Jambor, 1978).

Often parents wonder whether a preschooler who spends much time playing alone is developing normally. But only *certain types* of nonsocial activity—aimless wandering, hovering near peers, and functional play involving repetitive motor action—are cause for concern. Children who behave reticently, by watching peers without playing, are usually temperamentally inhibited—high in social fearfulness (Coplan & Ooi, 2014). And preschoolers who engage in solitary, repetitive behavior (banging blocks, making a doll jump up and down) tend to be immature, impulsive children who find it difficult to regulate anger and aggression (Coplan et al., 2001). In the classroom, both reticent and impulsive children tend to experience peer ostracism (Coplan & Arbeau, 2008).

But other preschoolers with low rates of peer interaction are not socially anxious or impulsive. They simply like to play alone, and their solitary activities are positive and constructive. Children who prefer solitary play with art materials, puzzles, and building toys are typically well-adjusted youngsters who, when they do play with peers, show socially skilled behavior (Coplan & Armer, 2007). Still, a few preschoolers who engage in such age-appropriate solitary play—more often boys—are rebuffed by peers (Coplan et al., 2001, 2004). Perhaps because quiet play is inconsistent with the “masculine” gender role, boys who engage in it are at risk for negative reactions from both parents and peers and, eventually, for adjustment problems.

As noted in Chapter 7, *sociodramatic play*—an advanced form of cooperative play—becomes especially common over the preschool years. In joint make-believe, preschoolers act out and respond to one another's pretend feelings. They also explore and gain control of fear-arousing experiences when they play doctor or pretend to search for monsters in a magical forest. As a result, sociodramatic play helps them understand others' feelings and regulate their own (Meyers & Berk, 2014). Furthermore, preschoolers spend much time negotiating roles and rules in socio-

**TABLE 8.1**  
Developmental Sequence of Cognitive Play Categories

PLAY CATEGORY	DESCRIPTION	EXAMPLES
Functional play	Simple, repetitive motor movements with or without objects, especially common during the first two years	Running around a room, rolling a car back and forth, kneading clay with no intent to make something
Constructive play	Creating or constructing something, especially common between 3 and 6 years	Making a house out of toy blocks, drawing a picture, putting together a puzzle
Make-believe play	Acting out everyday and imaginary roles, especially common between 2 and 6 years	Playing house, school, or police officer; acting out storybook or television characters

Source: Rubin, Fein, & Vandenberg, 1983.

dramatic play. To create and manage complex plots, they must resolve disputes through compromise.

When researchers observed free-play periods in preschools, they found that girls participated more in sociodramatic play, whereas boys participated more in friendly, vigorous interactions called *rough-and-tumble play*. Each type of play was associated with expressions of positive emotion and predicted children's emotional understanding and self-regulation one year later (Lindsey & Colwell, 2013). Both sociodramatic play and rough-and-tumble play require children to exercise self-control and to respond to peers' verbal and nonverbal emotional cues. We will return to the topic of rough-and-tumble play in Chapter 11.

**Cultural Variations.** Peer sociability takes different forms, depending on the relative importance cultures place on group harmony as opposed to individual autonomy (Chen, 2012). For example, children in India generally play in large groups. Much of their behavior is imitative, occurs in unison, and involves close physical contact—a play style requiring high levels of cooperation. In a game called Bhatto Bhatto, children act out a script about a trip to the market, touching one another's elbows and hands as they pretend to cut and share a tasty vegetable (Roopnarine et al., 1994).

As another example, young Chinese children—unlike their North American agemates, who tend to reject reticent peers—are typically accepting of quiet, reserved behavior by their playmates (Chen et al., 2006; French et al., 2011). In Chapter 6, we saw that until recently, cultural values that discourage self-assertion led to positive evaluations of shyness in China (see page 195). Apparently, this benevolent attitude is still evident in the play behaviors of young Chinese children.

Cultural beliefs about the importance of play also affect early peer associations. Caregivers who view play as mere entertainment are less likely to provide props or to encourage pretend than those who value its cognitive and social benefits (Gaskins, 2014). Recall the description of children's daily lives in a Mayan village culture on page 237 in Chapter 7. When Mayan children do pretend, their play themes are *interpretive* of daily life—involving a limited number of scripts that reflect everyday roles and experiences. Children in industrialized, urban contexts more often engage in *inventive* play, generating make-believe scenarios unconstrained by actual experience (Gaskins, 2013). Perhaps Western-style sociodramatic play, with its elaborate materials and wide-ranging imaginative themes, is particularly important for social development in societies where the worlds of adults and children are distinct. It may be less crucial in village cultures where children participate in adult activities from an early age.

## First Friendships

As preschoolers interact, first friendships form that serve as important contexts for emotional and social development. To adults, friendship is a mutual relationship involving companionship, sharing, understanding of thoughts and feelings, and caring for and comforting each other in times of need. In addition, mature friendships endure over time and survive occasional conflicts.

Preschoolers understand something about the uniqueness of friendship. They say that a friend is someone “who likes you,” with whom you spend a lot of time playing, and with whom you share toys. But friendship does not yet have a long-term, enduring quality based on mutual trust (Damon, 1988a; Hartup, 2006). “Mark’s my best friend,” Sammy declared on days when the boys got along well. But when a dispute arose, he reversed himself: “Mark, you’re not my friend!” Nevertheless, preschool friendships can be remarkably stable across early childhood, as long as peers remain in the same social group. In one study, nearly one-third mentioned the same best friends—the children they like to play with most—a year later (Dunn, 2004a; Eivers et al., 2012).

Already, interactions between preschoolers who mutually name each other as friends are especially positive, reflecting greater support and intimacy than do other peer relationships (Furman & Rose, 2015; Hartup, 2006). Preschoolers give far more reinforcement—greetings, praise, and compliance—to their friends, and they also receive more from them. Friends are also more cooperative and emotionally expressive—talking, laughing, and looking at each other more often than nonfriends do.

As early as the preschool years, children with a mutual friendship are better adjusted and more socially competent (Shin et al., 2014). Furthermore, children entering kindergarten who have friends in their class or who readily make new friends adjust to school more favorably (Ladd, Birch, & Buhs, 1999; Proulx & Poulin, 2013). Perhaps the company of friends serves as a secure base from which to develop new relationships, enhancing children's feelings of comfort in the new classroom.

© JACOB MAENTZ/CORBIS

Agta village children in the Philippines play a tug-of-war game. Large-group, highly cooperative play occurs more often in societies that value group harmony over individual autonomy.

## Peer Relations and School Readiness

The ease with which kindergartners make new friends and are accepted by classmates predicts cooperative participation in classroom activities and self-directed completion of learning tasks (Ladd, Buhs, & Seid, 2000). Socially competent preschoolers are more motivated and persistent, exceeding their less socially skilled peers in academic performance in kindergarten and the early school grades (Walker & Henderson, 2012; Ziv, 2013). Because social maturity in early childhood contributes to academic performance, readiness for kindergarten must be assessed in terms of not only academic skills but also social skills.

Young children's positive peer interactions occur most often in unstructured situations such as free play, making it important for preschools and kindergartens to provide space, time, materials, and adult scaffolding to support child-directed activities (Booren, Downer, & Vitiello, 2012). Warm, responsive teacher-child interaction is also vital, especially for shy children and for impulsive, emotionally negative, and aggressive children, who are at high risk for social difficulties (Brendgen et al., 2011; Vitaro et al., 2012). In studies involving several thousand 4-year-olds in public preschools in six states, teacher sensitivity and emotional support were strong predictors of children's social competence, both during preschool and in a follow-up after kindergarten entry (Curby et al., 2009; Mashburn et al., 2008). Along with excellent teacher preparation, other indicators of program quality—small group sizes, generous teacher-child ratios, and developmentally appropriate daily activities (see page 248 in Chapter 7)—create classroom conditions that make positive teacher and peer relationships more likely.

## Parental Influences on Early Peer Relations

Children first acquire skills for interacting with peers within the family. Parents influence children's peer sociability both *directly*, through attempts to influence children's peer relations, and *indirectly*, through their child-rearing practices and play.

**Direct Parental Influences.** Preschoolers whose parents frequently arrange informal peer play activities tend to have larger peer networks and to be more socially skilled (Ladd, LeSieur, & Profilet, 1993). In providing play opportunities, parents show children how to initiate peer contacts. And parents' skillful suggestions for managing conflict, discouraging teasing, and entering a play group are associated with preschoolers' social competence and peer acceptance (Mize & Pettit, 2010; Parke et al., 2004).

**Indirect Parental Influences.** Many parenting behaviors not directly aimed at promoting peer sociability nevertheless influence it. For example, secure attachments to parents are linked to more responsive, harmonious peer interaction, larger peer networks, and warmer, more supportive friendships during the

© LAURA DWIGHT PHOTOGRAPHY

Parents' play with children, especially same-sex children, contributes to social competence. By playing with his father as he would with a peer, this child acquires social skills that facilitate peer interaction.

preschool and school years (Laible, 2007; Lucas-Thompson & Clarke-Stewart, 2007; Wood, Emmerson, & Cowan, 2004). The sensitive, emotionally expressive communication that contributes to attachment security is likely responsible.

Warm, collaborative parent-child play seems particularly effective for promoting peer interaction skills. During play, parents interact with their child on a "level playing field," much as peers do. And perhaps because parents play more with children of their own sex, mothers' play is more strongly linked to daughters' competence, fathers' play to sons' competence (Lindsey & Mize, 2000; Pettit et al., 1998).

As we have seen, some preschoolers already have great difficulty with peer relations. In Leslie's classroom, Robbie was one of them. Wherever he happened to be, comments like "Robbie ruined our block tower" and "Robbie hit me for no reason" could be heard. As we take up moral development and aggression in the next section, you will learn more about how parenting contributed to Robbie's peer problems.

## Ask yourself

**CONNECT** How does emotional self-regulation affect the development of empathy and sympathy? Why are these emotional capacities vital for positive peer relations?

**APPLY** Three-year-old Ben lives in the country, with no other preschoolers nearby. His parents wonder whether it is worth driving Ben into town once a week to participate in a peer play group. What advice would you give Ben's parents, and why?

**REFLECT** What did your parents do, directly and indirectly, that might have influenced your earliest peer relationships?

## Foundations of Morality and Aggression

**8.5** What are the central features of psychoanalytic, social learning, and cognitive-developmental approaches to moral development?

**8.6** Describe the development of aggression in early childhood, including family and media influences and effective approaches to reducing aggressive behavior.

Young children's behavior provides many examples of their budding moral sense. We have seen that toddlers show empathic concern for others in distress and will try to help. They also expect others to act fairly, by dividing resources equally among peers (Geraci & Surian, 2011). As children reach age 2, they often use language to evaluate their own and others' actions: "I naughty. I wrote on the wall" or (after being hit by another child) "Connie not nice." And we have seen that children of this age share toys, help others, and cooperate in games—early indicators of considerate, responsible, prosocial attitudes.

Adults everywhere take note of this developing capacity to distinguish right from wrong. Some cultures have special terms for it. The Utku Indians of Hudson Bay say the child develops *ihuma* (reason). The Fijians believe that *vakayalo* (sense) appears. In response, parents hold children more responsible for their actions (Dunn, 2005). By the end of early childhood, children can state many moral rules: "Don't take someone's things without asking!" "Tell the truth!" In addition, they argue over matters of justice: "You sat there last time, so it's my turn." "It's not fair. He got more!"

All theories of moral development recognize that conscience begins to take shape in early childhood. And most agree that at first, the child's morality is *externally controlled* by adults. Gradually, it becomes regulated by *inner standards*. Truly moral individuals do not do the right thing just to conform to others' expectations. Rather, they have developed compassionate concerns and principles of good conduct, which they follow in many situations.

Each major theory of development emphasizes a different aspect of morality. Psychoanalytic theory stresses the *emotional side* of conscience development—in particular, identification and guilt as motivators of good conduct. Social learning theory focuses on how *moral behavior* is learned through reinforcement and modeling. Finally, the cognitive-developmental perspective emphasizes *thinking*—children's ability to reason about justice and fairness.

### The Psychoanalytic Perspective

Recall that according to Freud, young children form a *superego*, or conscience, by *identifying* with the same-sex parent, whose moral standards they adopt. Children obey the superego to avoid *guilt*, a painful emotion that arises each time they are tempted to misbehave. Moral development, Freud believed, is largely complete by 5 to 6 years of age.

Today, most researchers disagree with Freud's view of conscience development. In his theory (see page 14), fear of punishment and loss of parental love motivate conscience formation and moral behavior. Yet children whose parents frequently use threats, commands, or physical force tend to violate standards often and feel little guilt (Kochanska et al., 2005, 2008). And if a parent withdraws love after misbehavior—for example, refuses to speak to or states a dislike for the child—children often respond with high levels of self-blame, thinking "I'm no good" or "Nobody loves me." Eventually, to protect themselves from overwhelming guilt, these children may deny the emotion and, as a result, also develop a weak conscience (Kochanska, 1991; Zahn-Waxler et al., 1990).

**Inductive Discipline.** In contrast, conscience formation is promoted by a type of discipline called **induction**, in which an adult helps make the child aware of feelings by pointing out the effects of the child's misbehavior on others. For example, a parent might say, "She's crying because you won't give back her doll" (Hoffman, 2000). When generally warm parents provide explanations that match the child's capacity to understand, while firmly insisting that the child listen and comply, induction is effective as early as age 2. Preschoolers whose parents use it are more likely to refrain from wrongdoing, confess and repair damage after misdeeds, and display prosocial behavior (Choe, Olson, & Sameroff, 2013; Volling, Mahoney, & Rauer, 2009).

The success of induction may lie in its power to motivate children's active commitment to moral standards. Induction gives children information about how to behave that they can use in future situations. By emphasizing the impact of the child's actions on others, it encourages empathy and sympathetic concern. And giving children reasons for changing their behavior encourages them to adopt moral standards because those standards make sense.

In contrast, discipline that relies too heavily on threats of punishment or withdrawal of love makes children so anxious and

© LAURA DWIGHT PHOTOGRAPHY

A teacher uses inductive discipline to explain to a child the impact of her transgression on others, pointing out classmates' feelings. Induction encourages empathy, sympathetic concern, and commitment to moral standards.

frightened that they cannot think clearly enough to figure out what they should do. As a result, these practices do not get children to internalize moral rules and—as noted earlier—also interfere with empathy and prosocial responding (Eisenberg, Spinrad, & Knafo-Noam, 2015).

**The Child's Contribution.** Although good discipline is crucial, children's characteristics also affect the success of parenting techniques. Twin studies suggest a modest genetic contribution to empathy (Knafo et al., 2009). More empathic children require less power assertion and are more responsive to induction.

Temperament is also influential. Mild, patient tactics—requests, suggestions, and explanations—are sufficient to prompt guilt reactions in anxious, fearful preschoolers (Kochanska et al., 2002). But with fearless, impulsive children, gentle discipline has little impact. Power assertion also works poorly. It undermines children's effortful control, or capacity to regulate their emotional reactivity, which is linked to good conduct, empathy, sympathy, and prosocial behavior (Kochanska & Aksan, 2006). Parents of impulsive children can foster conscience development by ensuring a warm, harmonious relationship and combining firm correction of misbehavior with induction (Kochanska & Kim, 2014). When children are so low in anxiety that parental disapproval causes them little discomfort, a close parent-child bond motivates them to listen to parents as a means of preserving an affectionate, supportive relationship.

**The Role of Guilt.** Although little support exists for Freudian ideas about conscience development, Freud was correct that guilt motivates moral action. Inducing *empathy-based guilt*—expressions of personal responsibility and regret, such as “I’m sorry I hurt him”—by explaining that the child is harming someone and has disappointed the parent is particularly effective (Eisenberg, Eggum, & Edwards, 2010). Empathy-based guilt reactions are associated with stopping harmful actions, repairing damage caused by misdeeds, and engaging in future prosocial behavior.

But contrary to what Freud believed, guilt is not the only force that compels us to act morally. Nor is moral development complete by the end of early childhood. Rather, it is a gradual process that extends into adulthood.

## Social Learning Theory

According to social learning theory, morality does not have a unique course of development. Rather, moral behavior is acquired through modeling, just like any other set of responses.

**Importance of Modeling.** Many studies show that having helpful or generous models increases young children's prosocial responses. Nevertheless, certain characteristics of models affect children's willingness to imitate:

- *Warmth and responsiveness.* Preschoolers are more likely to copy the prosocial actions of warm, responsive (as opposed to cold, distant) adults (Yarrow, Scott, & Waxler, 1973).

Warmth seems to make children more attentive and receptive to the model and is itself an example of a prosocial response.

- *Competence and power.* Children admire and therefore tend to imitate competent, powerful models—especially older peers and adults (Bandura, 1977).
- *Consistency between assertions and behavior.* When models say one thing and do another—for example, announce that “it’s important to help others” but rarely engage in helpful acts—children generally choose the most lenient standard of behavior (Mischel & Liebert, 1966).

Models are most influential in the early years. In one study, toddlers' eager, willing imitation of their mothers' behavior predicted moral conduct (not cheating in a game) and guilt following transgressions at age 3 (Forman, Aksan, & Kochanska, 2004). At the end of early childhood, children who have had consistent exposure to caring adults tend to behave prosocially whether or not a model is present (Mussen & Eisenberg-Berg, 1977). They have internalized prosocial rules from repeated observations and encouragement by others.

At the same time, reinforcing young children with attention or praise appears unnecessary to induce them to help others. Most 2-year-olds will readily help an unfamiliar adult obtain an out-of-reach object, regardless of whether their parent encourages them, remains silent, or is absent from the room (Warneken & Tomasello, 2013). And giving children material rewards for helping undermines their prosocial responding (Warneken & Tomasello, 2009). Children who are materially rewarded come to expect something in return for helping and, therefore, rarely help spontaneously, out of kindness to others.

**Effects of Punishment.** Many parents realize that yelling at, slapping, and spanking children for misbehavior are ineffective disciplinary tactics. A sharp reprimand or physical force to restrain or move a child is justified when immediate obedience is necessary—for example, when a 3-year-old is about to run into the street. In fact, parents are most likely to use forceful methods under these conditions. But to foster long-term goals, such as acting kindly toward others, they tend to rely on warmth and reasoning (Kuczynski, 1984; Lansford et al., 2012). And in response to serious transgressions, such as lying and stealing, they often combine power assertion with reasoning (Grusec, 2006).

Frequent punishment promotes immediate compliance but not lasting changes in behavior. For example, Robbie's parents often punished by hitting, shouting, and criticizing. But as soon as they stopped punishing and turned away, Robbie—like most children subjected to corporal punishment—misbehaved again (Holden, Williamson, & Holland, 2014). The more harsh threats, angry physical control, and physical punishment children experience, the more likely they are to develop serious, lasting problems. These include weak internalization of moral rules; depression, aggression, antisocial behavior, and poor academic performance in childhood and adolescence; and depression, alcohol abuse, criminality, physical health problems, and family

violence in adulthood (Afifi et al., 2013; Bender et al., 2007; Kochanska, Aksan, & Nichols, 2003).

Repeated harsh punishment has wide-ranging undesirable side effects:

- Parents often spank in response to children's aggression. Yet the punishment itself models aggression!
- Harshly treated children develop a chronic sense of being personally threatened, which prompts a focus on their own distress rather than a sympathetic orientation to others' needs.
- Children who are frequently punished learn to avoid the punitive parent, who, as a result, has little opportunity to teach desirable behaviors.
- By stopping children's misbehavior temporarily, harsh punishment gives adults immediate relief. For this reason, a punitive adult is likely to punish with greater frequency over time, a course of action that can spiral into serious abuse.
- Children, adolescents, and adults whose parents used *corporal punishment*—physical force that inflicts pain but not injury—are more accepting of such discipline (Deater-Deckard et al., 2003; Vitrup & Holden, 2010). In this way, use of physical punishment may transfer to the next generation.

Although corporal punishment spans the SES spectrum, its frequency and harshness are elevated among less-educated, economically disadvantaged parents (Giles-Sims, Straus, & Sugarman, 1995; Lansford et al., 2009). And consistently, parents with conflict-ridden marriages and with mental health problems (who are emotionally reactive, depressed, or aggressive) are more likely to be punitive and also to have hard-to-manage children, whose disobedience evokes more parental harshness (Berlin et al., 2009; Taylor et al., 2010). But even after controlling for child, parenting, and family characteristics that might otherwise account for the relationship, longitudinal findings reveal a link between physical punishment and later child and adolescent aggression (Lansford et al., 2011; Lee et al., 2013; MacKenzie et al., 2013).

Physical punishment affects children with certain temperaments more than others. In a longitudinal study extending from 15 months to 3 years, early corporal punishment predicted externalizing behavior in preschoolers of diverse temperaments, but negative outcomes were considerably greater for temperamentally difficult children (Mulvaney & Mebert, 2007). Similar findings emerged in a twin study in which physical punishment was most detrimental for children at high genetic risk for behavior problems (Boutwell et al., 2011). Return to page 70 in Chapter 2 to review findings indicating that good parenting can shield children at risk for aggression and antisocial activity from developing those behaviors.

In view of these findings, the widespread use of corporal punishment by American parents is cause for concern. Surveys of nationally representative samples of U.S. families reveal that

**FIGURE 8.1** Prevalence of corporal punishment in early and middle childhood by year of survey. Five large surveys of U.S. parents show little change in use of corporal punishment over nearly three decades. Estimates are based on the number of parents per 1,000 reporting one or more instances of spanking or slapping their child during the past year. Rates are not shown for infants and toddlers, though other evidence indicates that 50 to 80 percent experience physical punishment. (From A. J. Zolotor, A. D. Theodore, D. K. Runyan, J. J. Chang, & A. L. Laskey, 2011, "Corporal Punishment and Physical Abuse: Population-Based Trends for Three- to 11-Year-Old Children in the United States," *Child Abuse Review*, 20, p. 61. Reprinted by permission of John Wiley & Sons, Ltd.)

although corporal punishment typically increases from infancy to age 5 and then declines, it is high at all ages (see Figure 8.1) (Gershoff et al., 2012; Straus & Stewart, 1999; Zolotor et al., 2011). Furthermore, more than one-third of physically punishing parents report having used a hard object, such as a brush or a belt.

A prevailing American belief is that corporal punishment, if implemented by caring parents, is harmless, perhaps even beneficial. But as the Cultural Influences box on page 270 reveals, this assumption is valid only under conditions of limited use in certain social contexts.

**Alternatives to Harsh Punishment.** Alternatives to criticism, slaps, and spankings can reduce the side effects of punishment. A technique called **time out** involves removing children from the immediate setting—for example, by sending them to their rooms—until they are ready to act appropriately. When a child is out of control, a few minutes in time out can be enough to change behavior while also giving angry parents time to cool off (Morawska & Sanders, 2011). Another approach is *withdrawal of privileges*, such as watching a favorite TV program. Like time out, removing privileges allows parents to avoid using harsh techniques that can easily intensify into violence.

When parents do decide to use mild punishment, they can increase its effectiveness in three ways:

- **Consistency.** Permitting children to act inappropriately on some occasions but scolding them on others confuses them, and the unacceptable act persists (Acker & O'Leary, 1996).

## Cultural Influences

### Ethnic Differences in the Consequences of Physical Punishment

In an African-American community, six older adults, who had volunteered to serve as mentors for parents facing child-rearing challenges, met to discuss parenting issues at a social service agency. Their attitudes toward discipline were strikingly different from those of the white social workers who had brought them together. Each mentor argued that successful child rearing required appropriate physical tactics. At the same time, they voiced strong disapproval of screaming or cursing at children, calling such out-of-control parental behavior “abusive.” Ruth, the oldest and most respected member of the group, characterized good parenting as a complex combination of warmth, teaching, talking nicely, and disciplining physically. She related how an older neighbor advised her to handle her own children when she was a young parent:

She said to me says, don't scream ... you talk to them real nice and sweet and when they do something ugly ... she say you get a nice little switch and you won't have any trouble with them and from that day that's the way I raised 'em. (Mosby et al., 1999, pp. 511–512)

In several studies, corporal punishment predicted externalizing problems similarly among white, black, Hispanic, and Asian children (Gershoff et al., 2012; MacKenzie et al., 2013). But other studies point to ethnic variations. In one longitudinal investigation, researchers followed several hundred families, collecting information from mothers on disciplinary strategies and from teachers on children's problem behaviors from kindergarten through fourth grade (Lansford et al., 2012). Regardless of ethnicity, reasoning was the most common approach to discipline, spanking the least common. But predictors and outcomes of spanking varied, depending on family ethnicity.

Among white families, externalizing behavior in kindergarten predicted parental physical punishment in first through third grades, which in turn led to more externalizing behavior by fourth grade. In contrast, among African-American families, kindergarten externalizing

© LAURA DWIGHT PHOTOGRAPHY

In African-American families, physical discipline is often culturally approved, generally mild, and delivered in a context of parental warmth. As a result, children may view it as an effort to encourage maturity, not as an act of aggression.

behavior was unrelated to later physical punishment, and physical punishment did not augment externalizing behavior (Lansford et al., 2012). The investigators concluded that white parents more often use physical discipline in reaction to challenging behaviors, causing those behaviors to escalate. African-American parents, in contrast, seem to use physical punishment to prevent child difficulties, thereby reducing its negative consequences.

Consistent with this interpretation, African-American and European-American parents report meting out physical punishment differently. In black families, such discipline is typically culturally approved, mild, delivered in a context of parental warmth, accompanied by verbal teaching, and aimed at helping children become responsible adults. White parents, in contrast, usually consider physical punishment to be wrong, so when they resort to it, they are often highly agitated and rejecting of the child (Dodge, McLoyd, & Lansford, 2006; LeCuyer et al., 2011). As a result, most black children may view spanking as a practice carried out with their best interests in mind, whereas white children may regard it as an act of aggression.

In support of this view, when several thousand ethnically diverse children were followed from the preschool through the early school years, spanking was associated with a rise in behavior problems if parents were cold and rejecting, but not if they were warm and supportive (McLoyd & Smith, 2002). In another study, spanking predicted depressive symptoms only among a small number of African-American children whose mothers disapproved of the practice and, as a result, tended to use it when they were highly angry and frustrated (McLoyd et al., 2007).

These findings are not an endorsement of physical punishment. Other forms of discipline, including time out, withdrawal of privileges, and the positive parenting strategies listed on page 271, are far more effective. In adolescence, ethnic differences in physical punishment fade: It is broadly associated with depression and misconduct among teenagers (Wang & Kenny, 2014). But it is noteworthy that the meaning and impact of physical discipline to children can vary sharply with its intensity level, context of warmth and support, and cultural approval.

## Applying what we Know

### Positive Parenting

STRATEGY	EXPLANATION
Use transgressions as opportunities to teach.	When a child engages in harmful or unsafe behavior, intervene firmly, and then use induction, which motivates children to make amends and behave prosocially.
Reduce opportunities for misbehavior.	On a long car trip, bring back-seat activities that relieve children's restlessness. At the supermarket, converse with children and let them help with shopping. Children then learn to occupy themselves constructively when options are limited.
Provide reasons for rules.	When children appreciate that rules are rational, not arbitrary, they are more likely to strive to follow the rules.
Arrange for children to participate in family routines and duties.	By joining with adults in preparing a meal, clearing the table, or raking leaves, children develop a sense of responsible participation in family and community life and acquire many practical skills.
When children are obstinate, try compromising and problem solving.	When a child refuses to obey, express understanding of the child's feelings ("I know it's not fun to clean up"), suggest a compromise ("You put those away, I'll take care of these"), and help the child think of ways to avoid the problem in the future. Responding firmly but kindly and respectfully increases the likelihood of willing cooperation.
Encourage mature behavior.	Express confidence in children's capacity to learn and appreciation for effort and cooperation: "You gave that your best!" "Thanks for cleaning up on your own!" Adult encouragement fosters pride and satisfaction in succeeding, thereby inspiring children to improve further.

Sources: Berk, 2001; Grusec, 2006.

- *A warm parent–child relationship.* Children of involved, caring parents find the interruption in parental affection that accompanies punishment especially unpleasant. They want to regain parental warmth and approval as quickly as possible.
- *Explanations.* Providing reasons for mild punishment helps children relate the misdeed to expectations for future behavior (Larzelere et al., 1996). This approach leads to a far greater reduction in misbehavior than using punishment alone.

**Positive Relationships, Positive Parenting.** The most effective forms of discipline encourage good conduct—by building a mutually respectful bond with the child, letting the child know ahead of time how to act, and praising mature behavior. When sensitivity, cooperation, and shared positive emotion are evident in joint activities between parents and preschoolers, children show firmer conscience development—expressing empathy after transgressions, playing fairly in games, and considering others' welfare (Kochanska et al., 2008; Thompson, 2014). Parent–child closeness leads children to heed parental demands because the child feels a sense of commitment to the relationship.

See Applying What We Know above for ways to parent positively. After experiencing a training program in these strategies, parents felt more confident about their ability to handle child-rearing challenges and were less approving of physical punish-

ment (Durrant et al., 2014). When parents focus on promoting children's long-term social and life skills—cooperation, problem solving, and consideration for others—they greatly reduce the need for punishment.

## The Cognitive-Developmental Perspective

The psychoanalytic and behaviorist approaches to morality focus on how children acquire ready-made standards of good conduct from adults. In contrast, the cognitive-developmental perspective regards children as *active thinkers* about social rules. As early as the preschool years, children make moral judgments, deciding what is right or wrong on the basis of concepts they construct about justice and fairness (Gibbs, 2010; Helwig & Turiel, 2011).

Young children have some well-developed ideas about morality. As long as researchers emphasize people's intentions, 3-year-olds say that a person with bad intentions—someone who deliberately frightens, embarrasses, or otherwise hurts another—is more deserving of punishment than a well-intentioned person. They also protest when they see one person harming another (Helwig, Zelazo, & Wilson, 2001; Vaish, Missana, & Tomasello, 2011). Around age 4, children know that a person who expresses an insincere intention—saying, "I'll come over and help you rake leaves," while not intending to do so—is lying (Maas, 2008). And 4-year-olds approve of telling the truth and disapprove of lying, even when a lie remains undetected (Bussey, 1992).

© JEFF GREENBERG/PHOTOEDIT

This preschooler understands that his choice of a toy is a matter of personal choice, distinct from moral imperatives and social conventions.

Furthermore, preschoolers distinguish **moral imperatives**, which protect people's rights and welfare, from two other types of rules and expectations: **social conventions**, customs determined solely by consensus, such as table manners and politeness rituals (saying "please" and "thank you"); and **matters of personal choice**, such as choice of friends, hairstyle, and leisure activities, which do not violate rights and are up to the individual (Killen, Margie, & Sinno, 2006; Nucci & Gingo, 2011; Smetana, 2006). Interviews with 3- and 4-year-olds reveal that they consider moral violations (stealing an apple) as more wrong than violations of social conventions (eating ice cream with your fingers). And preschoolers' concern with personal choice, conveyed through statements like "I'm gonna wear *this* shirt," serves as the springboard for moral concepts of individual rights, which will expand greatly in middle childhood and adolescence.

Young children's moral reasoning tends to be *rigid*, emphasizing salient features and consequences while neglecting other important information. For example, they have difficulty distinguishing between accidental and intentional transgressions (Killen et al., 2011). And they are more likely than older children to claim that stealing and lying are always wrong, even when a person has a morally sound reason for engaging in these acts (Lourenço, 2003). Furthermore, their explanations for why hitting others is wrong are simplistic and centered on physical harm: "When you get hit, it hurts, and you start to cry" (Nucci, 2008).

Still, preschoolers' ability to distinguish moral imperatives from social conventions is impressive. Researchers speculate that children's commitment to the wrongness of moral transgressions builds on their early concern for others' welfare. With language and cognitive development—especially, in theory of mind and in understanding of emotion—older preschoolers start to reason morally by referring to others' perspectives and feelings. In

several studies, understanding of false belief was associated with 4- and 5-year-olds' moral justifications that focused on the harmed individual's emotions and well-being (Dunn, Cutting, & Demetriou, 2000; Lane et al., 2010). But advances in theory of mind, though influencing preschoolers' explanations, are not sufficient to account for gains in moral understanding.

In addition, morally relevant social experiences are vital, contributing to gains in both theory of mind and moral understanding and to their integration (Killen & Smetana, 2015). Disputes with siblings and peers over rights, possessions, and property allow preschoolers to express emotions and perspectives, negotiate, compromise, and work out their first ideas about justice and fairness. Children also learn from warm, sensitive parental communication and from observing how adults respond to children's rule violations (Turiel & Killen, 2010). Children who are advanced in moral thinking tend to have parents who adapt their discussions about fighting, honesty, and ownership to what their children can understand, tell stories with moral implications, point out injustices, encourage pro-social behavior, and gently stimulate the child to think further, without being hostile or critical (Dunn, 2014; Janssens & Deković, 1997).

Preschoolers who verbally and physically assault others, often with little or no provocation, are already delayed in moral reasoning (Helwig & Turiel, 2004). Without special help, such children show long-term disruptions in moral development, deficits in self-control, and ultimately an antisocial lifestyle.

## The Other Side of Morality: Development of Aggression

Beginning in late infancy, all children display aggression from time to time, and as opportunities to interact with siblings and peers increase, aggressive outbursts occur more often (Naerde et al., 2014). By the second year, aggressive acts with two distinct purposes emerge. Initially, the most common is **proactive** (or *instrumental*) **aggression**, in which children act to fulfill a need or desire—to obtain an object, privilege, space, or social reward, such as adult or peer attention—and unemotionally attack a person to achieve their goal. The other type, **reactive** (or *hostile*) **aggression**, is an angry, defensive response to provocation or a blocked goal and is meant to hurt another person (Eisner & Malti, 2015; Vitaro & Brendgen, 2012).

Proactive and reactive aggression come in three forms, which are the focus of most research:

- **Physical aggression** harms others through physical injury—pushing, hitting, kicking, or punching others, or destroying another's property.
- **Verbal aggression** harms others through threats of physical aggression, name-calling, or hostile teasing.
- **Relational aggression** damages another's peer relationships through social exclusion, malicious gossip, or friendship manipulation.

Although verbal aggression is always direct, physical and relational aggression can be either *direct* or *indirect*. For example, hitting injures a person directly, whereas destroying property inflicts physical harm indirectly. Similarly, saying, “Do what I say, or I won’t be your friend,” conveys relational aggression directly, while spreading rumors, refusing to talk to a peer, or manipulating friendships by saying behind someone’s back, “Don’t play with her; she’s a nerd,” do so indirectly.

Physical aggression rises sharply between ages 1 and 3 and then diminishes as verbal aggression replaces it (Alink et al., 2006; Vitaro & Brendgen, 2012). And proactive aggression declines as preschoolers’ improved capacity to delay gratification enables them to resist grabbing others’ possessions. But reactive aggression in verbal and relational forms tends to rise over early and middle childhood (Côté et al., 2007; Tremblay, 2000). Older children are better able to recognize malicious intentions and, as a result, more often retaliate in hostile ways.

By age 17 months, boys are more physically aggressive than girls—a difference found throughout childhood in many cultures (Baillargeon et al., 2007; Card et al., 2008). The sex difference is due in part to biology—in particular, to male sex hormones (androgens) and temperamental traits (activity level, irritability, impulsivity) on which boys exceed girls. Gender-role conformity is also important. For example, parents respond far more negatively to physical fighting in girls (Arnold, McWilliams, & Harvey-Arnold, 1998).

Although girls have a reputation for being both verbally and relationally more aggressive than boys, the sex difference is small (Crick, Ostrov, & Werner, 2006; Crick et al., 2006). Beginning in the preschool years, girls concentrate most of their

aggressive acts in the relational category. Boys inflict harm in more variable ways. Physically and verbally aggressive boys also tend to be relationally aggressive (Card et al., 2008). Therefore, boys display overall rates of aggression that are much higher than girls’.

At the same time, girls more often use indirect relational tactics that—in disrupting intimate bonds especially important to girls—can be particularly mean. Whereas physical attacks are usually brief, acts of indirect relational aggression may extend for hours, weeks, or even months (Nelson, Robinson, & Hart, 2005; Underwood, 2003). In one instance, a 6-year-old girl formed a “pretty-girls club” and—for nearly an entire school year—convinced its members to exclude several classmates by saying they were “dirty and smelly.”

An occasional aggressive exchange between preschoolers is normal. But children who are emotionally negative, impulsive, and disobedient and who score low in cognitive abilities—especially, language and executive function skills necessary for self-regulation—are at risk for early, high rates of physical or relational aggression (or both) that can persist. Persistent aggression, in turn, predicts later internalizing and externalizing difficulties and social skills deficits, including loneliness, anxiety, depression, peer relationship problems, and antisocial activity in middle childhood and adolescence (Côté et al., 2007; Eisner & Malti, 2015; Ostrov et al., 2013).

### The Family as Training Ground for Aggressive Behavior.

“I can’t control him, he’s impossible,” Robbie’s mother, Nadine, complained to Leslie one day. When Leslie asked if Robbie might be troubled by something happening at home, she discovered that his parents fought constantly and resorted to harsh, inconsistent discipline. Parental power assertion, critical remarks, physical punishment, and inconsistency are linked to aggression from early childhood through adolescence in many cultures, with most of these practices predicting both physical and relational forms (Côté et al., 2007; Gershoff et al., 2010; Kuppens et al., 2013; Nelson et al., 2013; Olson et al., 2011).

In families like Robbie’s, anger and punitiveness quickly create a conflict-ridden family atmosphere and an “out-of-control” child. The pattern begins with forceful discipline, which occurs more often with stressful life experiences (such as economic hardship or an unhappy marriage), parental mental health problems, or a temperamentally difficult child (Eisner & Malti, 2015). Typically, the parent threatens, criticizes, and punishes, and the child angrily resists until the parent “gives in,” so the behaviors repeat and escalate.

As these cycles generate anxiety and irritability among other family members, they join in the hostile interactions. Compared with siblings in typical families, preschool siblings who have critical, punitive parents are more aggressive toward each other. Destructive sibling conflict, in turn, spreads to peer relationships, contributing to poor impulse control and antisocial behavior by the early school years (Miller et al., 2012a).

© BOB EBBESEN/ALAMY

These preschoolers display proactive aggression, pushing and grabbing as they argue over a game. As children learn to compromise and share, and as their capacity to delay gratification improves, proactive aggression declines.

Boys are more likely than girls to be targets of harsh, inconsistent discipline because they are more active and impulsive and therefore harder to control. When children who are extreme in these characteristics are exposed to emotionally negative, inept parenting, their capacity for emotional self-regulation, empathic responding, and guilt after transgressions is seriously disrupted (Eisenberg, Eggum, & Edwards, 2010). Consequently, they lash out when disappointed, frustrated, or faced with a sad or fearful victim.

Children subjected to these family processes acquire a distorted view of the social world, often seeing hostile intent where it does not exist and, as a result, making many unprovoked attacks (Lochman & Dodge, 1998; Orbio de Castro et al., 2002). And some, who conclude that aggression “works” to access rewards and control others, callously use it to advance their own goals and are unconcerned about causing suffering in others—an aggressive style associated with later more severe conduct problems, violent behavior, and delinquency (Marsee & Frick, 2010).

Highly aggressive children tend to be rejected by peers, to fail in school, and (by adolescence) to seek out deviant peers. Together, these factors contribute to the long-term stability of aggression. We will consider this life-course path of antisocial activity in Chapter 12.

**Media Violence and Aggression.** In the United States, an estimated 60 percent of TV programs contain violent scenes, often portraying repeated aggressive acts that go unpunished. TV victims of violence are rarely shown experiencing serious harm, and few programs condemn violence or depict other ways of solving problems (Calvert, 2015; Center for Communication and Social Policy, 1998). Verbally and relationally aggressive acts are particularly frequent in reality TV shows (Coyle, Robinson, & Nelson, 2010). And violent content is 10 percent above average in children’s programming, with cartoons being the most violent.

### LOOK and LISTEN

Watch a half-hour of cartoons and a prime-time movie on TV, and tally the number of violent acts, including those that go unpunished. How often did violence occur in each type of program? What do young viewers learn about the consequences of violence?

Reviewers of thousands of studies have concluded that TV violence increases the likelihood of hostile thoughts and emotions and of verbally, physically, and relationally aggressive behavior (Bushman & Huesmann, 2012; Comstock, 2008). A growing number of studies show that playing violent video and computer games has similar effects (Anderson et al., 2010; Hofferth, 2010). Although young people of all ages are susceptible, preschool and young school-age children are especially likely to imitate TV violence because they believe that much TV fiction is real and accept what they see uncritically.

© ALEX SEGRE/AMY

Watching TV violence increases the likelihood of hostile thoughts and emotions and aggressive behavior. Playing violent video and computer games has similar effects.

Violent programming not only creates short-term difficulties in parent and peer relations but also has lasting negative consequences. In several longitudinal studies, time spent watching TV in childhood and adolescence predicted aggressive behavior in adulthood, after other factors linked to TV viewing (such as prior child and parent aggression, IQ, parent education, family income, and neighborhood crime) were controlled (see Figure 8.2) (Graber et al., 2006; Huesmann et al., 2003; Johnson et al., 2002). Aggressive children and adolescents have a greater

**FIGURE 8.2** Relationship of television viewing in childhood and early adolescence to aggressive acts in adolescence and early adulthood. Interviews with more than 700 parents and youths revealed that the more TV watched in childhood and early adolescence, the greater the annual number of aggressive acts committed by the young person, as reported in follow-up interviews at ages 16 and 22. (Adapted from Johnson et al., 2002.)

## Applying what we Know

### Regulating Screen Media Use

STRATEGY	DESCRIPTION
Limit TV viewing and computer and tablet use.	Parents should provide clear rules limiting children's TV viewing and computer and tablet use, based on age guidelines and exposure to program and game content, and should stick to the rules. The TV or computer should not be used as a babysitter. Placing a TV or a computer in a child's bedroom substantially increases use and makes the child's activity hard to monitor.
Avoid using screen media as a reward.	When media access is used as a reward or withheld as a punishment, children become increasingly attracted to it.
When possible, watch TV and view online content with children, helping them understand what they see.	By raising questions about realism in media depictions, expressing disapproval of on-screen behavior, and encouraging discussion, adults help children understand and critically evaluate TV and online content.
Link TV and online content to everyday learning experiences.	Parents can extend TV and online learning in ways that encourage children to engage actively with their surroundings. For example, a program on animals might spark a trip to the zoo, a visit to the library for a book about animals, or new ways of observing and caring for the family pet.
Model good media practices.	Parents' media behavior influences children's behavior. Parents should avoid excessive media use, limit their own exposure to harmful content, and limit mobile device use during family interactions.

appetite for violent media fare. And boys devote more time to violent media than girls, in part because of male-oriented themes of conquest and adventure. But even in nonaggressive children, violent TV sparks hostile thoughts and behavior; its impact is simply less intense.

Surveys of U.S. parents indicate that 20 to 30 percent of preschoolers and about half of school-age children experience no limits on TV, computer, or tablet use (Rideout & Hamel, 2006; Roberts, Foehr, & Rideout, 2005; Varnhagen, 2007). And parents often model excessive, inappropriate use of screen media. In observations of adults with children in fast-food restaurants, almost one-third of the adults spent the entire meal absorbed with mobile devices rather than engaged with children in their care (Radesky et al., 2014).

To help parents improve their preschoolers' "media diet," one group of researchers devised a year-long intervention in which they guided parents in replacing violent programs with age-appropriate educational and prosocial programs. Compared to a control group, children in intervention families displayed lower rates of externalizing behavior and improved social competence (Christakis et al., 2013). Applying What We Know above lists strategies parents can use to regulate children's screen media use.

#### Helping Children and Parents Control Aggression.

Treatment for aggressive children is best begun early, before their behavior becomes well-practiced and difficult to change. Breaking the cycle of hostilities between family members and promoting effective ways of relating to others are crucial.

Leslie suggested that Robbie's parents enroll in a training program aimed at improving the parenting of children with

conduct problems. In one approach, called *Incredible Years*, parents complete 18 weekly group sessions facilitated by two professionals, who teach positive parenting techniques for promoting children's academic, emotional, and social skills and for managing disruptive behaviors (Webster-Stratton & Reid, 2010). A special focus is positive parenting, including guidance and encouragement for prosocial behaviors.

Evaluations in which families with aggressive children were randomly assigned to either *Incredible Years* or control groups reveal that the program is highly effective at improving parenting and reducing child behavior problems. And the effects endure. In one long-term follow-up, 75 percent of young children with serious conduct problems whose parents participated in *Incredible Years* were well-adjusted as teenagers (Webster-Stratton, Rinaldi, & Reid, 2011).

At preschool, Leslie began teaching Robbie more successful ways of relating to peers, had him practice these skills, and praised him for using them. As opportunities arose, she encouraged Robbie to talk about playmates' feelings and to express his own. As he increasingly took the perspective of others, empathized, and felt sympathetic concern, his lashing out at peers declined (Izard et al., 2008). Robbie also participated in a social problem-solving intervention. Throughout the school year, he met weekly with Leslie and a small group of classmates to act out common conflicts using puppets, discuss alternatives for settling disputes, and practice successful strategies. Preschoolers who receive such training show gains in emotional and social competence still present after entering kindergarten (Bierman & Powers, 2009; Moore et al., 2015).

Finally, relieving stressors that stem from economic disadvantage and neighborhood disorganization and providing

families with social supports help prevent childhood aggression (Bugental, Corpuz, & Schwartz, 2012). When parents better cope with stressors in their own lives, interventions aimed at reducing children's aggression are more effective.

## Ask yourself

**CONNECT** What must parents do to foster conscience development in fearless, impulsive children? How does this illustrate the concept of goodness of fit (see page 195 in Chapter 6)?

**APPLY** Alice and Wayne want their two children to become morally mature, caring individuals. List some parenting practices they should use and some they should avoid.

**REFLECT** Which types of punishment for a misbehaving preschooler do you endorse, and which types do you reject? Why?

## Gender Typing

**8.7** Discuss biological and environmental influences on preschoolers' gender-stereotyped beliefs and behavior.

**8.8** Describe and evaluate major theories that explain the emergence of gender identity.

**Gender typing** refers to any association of objects, activities, roles, or traits with one sex or the other in ways that conform to cultural stereotypes (Blakemore, Berenbaum, & Liben, 2009). In Leslie's classroom, girls spent more time in the housekeeping, art, and reading corners, while boys gathered more often in spaces devoted to blocks, woodworking, and active play. Already, the children had acquired many gender-linked beliefs and preferences and tended to play with peers of their own sex.

The same theories that provide accounts of morality have been used to explain children's gender typing: *social learning theory*, with its emphasis on modeling and reinforcement, and *cognitive-developmental theory*, with its focus on children as active thinkers about their social world. As we will see, neither is adequate by itself. *Gender schema theory*, a third perspective that combines elements of both, has gained favor. In the following sections, we consider the early development of gender typing.

## Gender-Stereotyped Beliefs and Behavior

Even before children can label their own sex consistently, they have begun to acquire common associations with gender—men as rough and sharp, women as soft and round. In one study, 18-month-olds linked such items as fir trees and hammers with males, although they had not yet learned comparable feminine

associations (Eichstedt et al., 2002). Recall from Chapter 6 that around age 2, children use such words as *boy*, *girl*, *lady*, and *man* appropriately. As soon as gender categories are established, young children's gender-typed learning accelerates.

Preschoolers associate toys, clothing, tools, household items, games, occupations, colors (pink and blue), and behaviors (physical and relational aggression) with one sex or the other (Banse et al., 2010; Giles & Heyman, 2005; Poulin-Dubois et al., 2002). And their actions reflect their beliefs, not only in play preferences but also in personality traits. As we have seen, boys tend to be more active, impulsive, assertive, and physically aggressive. Girls tend to be more fearful, dependent, emotionally sensitive, compliant, advanced in effortful control, and skilled at inflicting indirect relational aggression (Else-Quest, 2012).

During early childhood, gender-stereotyped beliefs strengthen—so much so that many children apply them as blanket rules rather than as flexible guidelines (Halim et al., 2013; Trautner et al., 2005). When children were asked whether gender stereotypes could be violated, half or more of 3- and 4-year-olds answered “no” to clothing, hairstyle, and play with certain toys (Barbie dolls and G.I. Joes) (Blakemore, 2003). Furthermore, most 3- to 6-year-olds are firm about not wanting to be friends with a child who violates a gender stereotype (a boy who wears nail polish, a girl who plays with trucks) or to attend a school where such violations are allowed (Ruble et al., 2007).

The rigidity of preschoolers' gender stereotypes helps us understand some commonly observed everyday behaviors. When Leslie showed her class a picture of a Scottish bagpiper wearing a kilt, the children insisted, “Men don't wear skirts!” During free play, they often exclaimed that girls can't be police officers and boys don't take care of babies. These one-sided judgments are a joint product of gender stereotyping in the environment and young children's cognitive limitations. Most

© LAURA DWIGHT PHOTOGRAPHY

Early in the preschool years, gender typing is well under way. Girls tend to play with girls and are drawn to toys and activities that emphasize nurturance and cooperation.

preschoolers do not yet realize that characteristics *associated with* being male or female—activities, toys, occupations, hair-style, and clothing—do not *determine* a person's sex.

## Biological Influences on Gender Typing

The sex differences in personality traits and behavior described earlier appear in many cultures around the world (Munroe & Romney, 2006; Whiting & Edwards, 1988). Certain ones—male activity level and physical aggression, female emotional sensitivity, and preference for same-sex playmates—are widespread among mammalian species (de Waal, 2001). According to an evolutionary perspective, the adult life of our male ancestors was largely oriented toward competing for mates, that of our female ancestors toward rearing children. Therefore, males became genetically primed for dominance and females for intimacy, responsiveness, and cooperativeness (Konner, 2010; Maccoby, 2002). Evolutionary theorists claim that family and cultural forces can influence the intensity of biologically based sex differences. But experience cannot eradicate those aspects of gender typing that served adaptive functions in human history.

Experiments with animals reveal that prenatally administered androgens increase active play and aggression and suppress maternal caregiving in both male and female mammals (Arnold, 2009). Research with humans reveals similar patterns. Girls exposed prenatally to high levels of androgens, due to normal variation in hormone levels or to a genetic defect, show more “masculine” behavior—a preference for trucks and blocks over dolls, for active over quiet play, and for boys as playmates—even when parents encourage them to engage in gender-typical play (Berenbaum & Beltz, 2011; Hines, 2011a). And boys with reduced prenatal androgen exposure, either because production by the testes is reduced or because body cells are androgen insensitive, tend to engage in “feminine” behaviors, including toy choices, play behaviors, and preference for girl playmates (Jürngensen et al., 2007; Lamminmaki et al., 2012).

Some researchers argue that biologically based sex differences, which affect children's play styles, cause children to seek out same-sex playmates whose interests and behaviors are compatible with their own (Maccoby, 1998; Mehta & Strough, 2009). Preschool girls like to play in pairs with other girls because they share a preference for quieter activities involving cooperative roles. Boys prefer larger-group play with other boys, due to a shared desire to run, climb, play-fight, compete, and build up and knock down.

Research confirms that preschoolers are drawn to peers who engage in similar levels of gender-typed activities. But they also like to spend time with same-sex peers regardless of type of activity—perhaps because they expect a playmate who is like themselves in so basic a way to be more enjoyable (Martin et al., 2013). At age 4, children spend three times as much time with same-sex as with other-sex playmates. By age 6, this ratio has climbed to 11 to 1 (Martin & Fabes, 2001).

## Environmental Influences on Gender Typing

A wealth of evidence reveals that environmental forces—at home, at school, with peers, and in the community—build on genetic influences to promote vigorous gender typing in early childhood.

**Parents.** Beginning at birth, parents have different expectations of sons than of daughters. Many parents prefer that their children play with “gender-appropriate” toys (Blakemore & Hill, 2008). And they tend to describe achievement, competition, and control of emotion as important for sons and warmth, polite behavior, and closely supervised activities as important for daughters (Brody, 1999; Turner & Gervai, 1995).

Actual parenting practices reflect these beliefs. Parents give their sons toys that stress action and competition (cars, tools, footballs) and their daughters toys that emphasize nurturance, cooperation, and physical attractiveness (dolls, tea sets, jewelry) (Leaper, 1994; Leaper & Friedman, 2007). Fathers of preschoolers report more physical activities (chasing, playing ball) with sons and more literacy activities (reading, storytelling) with daughters (Leavell et al., 2011). Furthermore, parents tend to react more positively when a son plays with cars and trucks, demands attention, runs and climbs, or tries to take toys from others. When interacting with daughters, parents more often direct play activities, provide help, encourage participation in household tasks, make supportive statements (approval, praise, and agreement), and refer to emotions (Clearfield & Nelson, 2006; Fagot & Hagan, 1991; Leaper, 2000).

Furthermore, parents provide children with indirect cues about gender stereotypes through the language they use. In a study of picture book reading with toddlers and preschoolers, mothers frequently expressed *generic utterances*, which referred

© LAURA DWIGHT PHOTOGRAPHY

This father teaches his son carpentry skills. Of the two sexes, boys are more gender-typed. Fathers, especially, promote “masculine” behavior in their sons by insisting that they conform to gender roles.

to nearly all same-sex individuals as alike, ignoring exceptions (“Boys can be sailors.” “Most girls don’t like trucks.”) (Gelman, Taylor, & Nguyen, 2004). Children picked up these expressions from their mother’s speech, and older preschoolers often made stereotyped generic statements, which their mothers affirmed (Child: “Only boys can drive trucks.” Mother: “O.K.”).

Of the two sexes, boys are more gender-typed. Fathers, especially, are more insistent that boys conform to gender roles. They place more pressure to achieve on sons than on daughters and are less tolerant of “cross-gender” behavior in sons—more concerned when a boy acts like a “sissy” than when a girl acts like a “tomboy” (Blakemore & Hill, 2008; Wood, Desmarais, & Gugula, 2002).

Parents who hold nonstereotyped values and behave accordingly have children who are less gender-typed (Tenenbaum & Leaper, 2002). Children of gay or lesbian parents tend to be less gender-typed than agemates of heterosexual parents, perhaps because of their parents’ more gender-equitable expectations and behaviors (Fulcher, Sutfin, & Patterson, 2008; Goldberg, Kashy, & Smith, 2012).

**Teachers.** Teachers often act in ways that extend gender-role learning. Several times, Leslie caught herself emphasizing gender distinctions when she called out, “Will the girls line up on one side and the boys on the other?” or pleaded, “Boys, I wish you’d quiet down like the girls!” These practices increase preschoolers’ gender-stereotyped beliefs while reducing their liking for and willingness to play with other-sex peers (Hilliard & Liben, 2010).

Like parents, preschool teachers encourage girls to participate in adult-structured activities. Girls frequently cluster around the teacher, following directions, while boys are attracted to play areas where adults are minimally involved (Campbell, Shirley, & Candy, 2004). As a result, boys and girls engage in different

social behaviors. Compliance and bids for help occur more often in adult-structured contexts; assertiveness, leadership, and creative use of materials in unstructured pursuits.

As early as kindergarten, teachers give more overall attention (both positive and negative) to boys than to girls—a difference evident in diverse countries, including China, England, and the United States. They praise boys more for their academic knowledge but also use more disapproval and controlling discipline with them (Chen & Rao, 2011; Davies, 2008; Swinson & Harrop, 2009). Teachers seem to expect boys to misbehave more often—a belief based partly on boys’ actual behavior and partly on gender stereotypes.

**Peers.** The more preschoolers play with same-sex partners, the more their behavior becomes gender-typed—in toy choices, activity level, aggression, and adult involvement (Martin et al., 2013). By age 3, same-sex peers positively reinforce one another for gender-typed play by praising, imitating, or joining in. In contrast, when preschoolers engage in “cross-gender” activities—for example, when boys play with dolls or girls with cars and trucks—peers criticize them. Boys are especially intolerant of cross-gender play in other boys (Thorne, 1993). A boy who frequently crosses gender lines is likely to be ignored by other boys, even when he does engage in “masculine” activities.

Children also develop different styles of social influence in gender-segregated peer groups. To get their way in large-group play, boys often rely on commands, threats, and physical force. Girls’ preference for playing in pairs leads to greater concern with a partner’s needs, evident in girls’ use of polite requests, persuasion, and acceptance. Girls soon find that gentle tactics succeed with other girls but not with boys, who ignore their courteous overtures (Leaper, 1994; Leaper, Tenenbaum, & Shaffer, 1999). Boys’ unresponsiveness gives girls another reason to stop interacting with them.

Over time, children come to believe in the “correctness” of gender-segregated play and to perceive themselves as more similar to same-sex than other-sex peers, which further strengthens gender segregation and gender-stereotyped activities (Martin et al., 2011). As boys and girls separate, *in-group favoritism*—more positive evaluations of members of one’s own gender—becomes another factor that sustains the separate social worlds of boys and girls, resulting in “two distinct subcultures” of knowledge, beliefs, interests, and behaviors (Maccoby, 2002).

Although gender segregation is pervasive, cultural variations exist in the extent of gender-typed communication within such groups. African-American and Hispanic girls from low-SES families tend to be more assertive and independent when interacting with one another and with boys than are European-American girls (Goodwin, 1998). Similarly, in a comparison of Chinese and U.S. preschoolers’ play, Chinese girls used more direct commands and criticism when interacting with same- and other-sex peers (Kyratzis & Guo, 2001). In cultures where interdependence is highly valued, perhaps children do not feel a need to work as hard at maintaining same-sex peer relations through traditional interaction.

© LAURA DWIGHT PHOTOGRAPHY

In this preschool classroom, girls cluster around the teacher for instruction while boys play independently. As a result, children practice gender-typed behaviors—compliance and bids for attention by girls, assertiveness and leadership by boys.

**The Broader Social Environment.** Finally, children’s everyday environments present many examples of gender-typed behavior—in occupations, leisure activities, media portrayals, and achievements of men and women. Media stereotypes, which are especially prevalent in cartoons and video games, contribute to young children’s biased beliefs about roles and behaviors suitable for males and females (Calvert, 2015; Leaper, 2013). As we will see next, children soon come to view not just their social surroundings but also themselves through a “gender-biased lens”—a perspective that can seriously restrict their interests and learning opportunities.

## Gender Identity

As adults, each of us has a **gender identity**—an image of oneself as relatively masculine or feminine in characteristics. By middle childhood, researchers can measure gender identity by asking children to rate themselves on personality traits. A child or adult with a “masculine” identity scores high on traditionally masculine items (such as *ambitious*, *competitive*, and *self-sufficient*) and low on traditionally feminine items (such as *affectionate*, *cheerful*, and *soft-spoken*). Someone with a “feminine” identity does the reverse. And a substantial minority (especially females) have a gender identity called **androgyny**, scoring high on both masculine and feminine personality characteristics.

Gender identity is a good predictor of psychological adjustment. “Masculine” and androgynous children and adults have higher self-esteem than “feminine” individuals (DiDonato & Berenbaum, 2011; Harter, 2012). Also, androgynous individuals are more adaptable—able to show masculine independence or feminine sensitivity, depending on the situation (Huyck, 1996; Taylor & Hall, 1982). The existence of an androgynous identity demonstrates that children can acquire a mixture of positive qualities traditionally associated with each gender—an orientation that may best help them realize their potential.

**Emergence of Gender Identity.** How do children develop a gender identity? According to *social learning theory*, behavior comes before self-perceptions. Preschoolers first acquire gender-typed responses through modeling and reinforcement and only later organize these behaviors into gender-linked ideas about themselves. In contrast, *cognitive-developmental theory* maintains that self-perceptions come before behavior. Over the preschool years, children acquire **gender constancy**—a full understanding of the biologically based permanence of their gender, including the realization that sex remains the same even if clothing, hairstyle, and play activities change. Then children use this knowledge to guide their gender-related behavior.

Children younger than age 6 who watch an adult dress a doll in “other-gender” clothing typically insist that the doll’s sex has also changed (Chauhan, Shastri, & Mohite, 2005; Fagot, 1985). Full attainment of gender constancy is strongly related to ability to pass Piagetian conservation tasks (DiLisi & Gallagher, 1991). Indeed, gender constancy tasks can be considered a type of

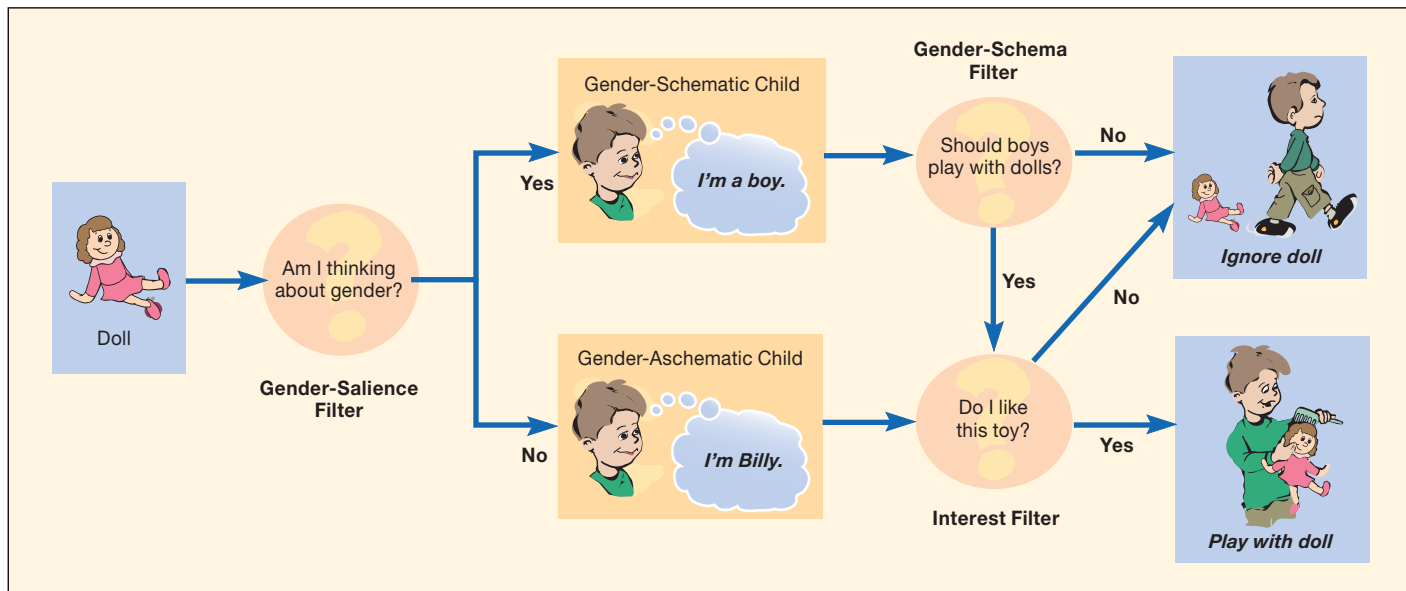

conservation problem, in that children must conserve a person’s sex despite a superficial change in his or her appearance.

Is cognitive-developmental theory correct that gender constancy is responsible for children’s gender-typed behavior? Evidence for this assumption is weak. Some evidence suggests that attaining gender constancy actually contributes to more flexible gender-role attitudes, perhaps because children then realize that engaging in gender-atypical behavior cannot cause their sex to change (Ruble et al., 2007). But overall, the impact of gender constancy on gender typing is not great. As research in the following section reveals, gender-role adoption is more powerfully affected by children’s beliefs about how close the connection must be between their own gender and their behavior.

**Gender Schema Theory.** **Gender schema theory** is an information-processing approach that combines social learning and cognitive-developmental features. It explains how environmental pressures and children’s cognitions work together to shape gender-role development (Martin & Halverson, 1987; Martin, Ruble, & Szkrybalo, 2002). At an early age, children pick up gender-stereotyped preferences and behaviors from others. At the same time, they organize their experiences into *gender schemas*, or masculine and feminine categories, that they use to interpret their world. As soon as preschoolers can label their own gender, they select gender schemas consistent with it (“Only boys can be doctors” or “Cooking is a girl’s job”) and apply those categories to themselves. Their self-perceptions then become gender-typed and serve as additional schemas that children use to process information and guide their own behavior.

We have seen that individual differences exist in the extent to which children endorse gender-typed views. Figure 8.3 on page 280 shows different cognitive pathways for children who often apply gender schemas to their experiences and those who rarely do (Liben & Bigler, 2002). Consider Billy, who encounters a doll. If Billy is a *gender-schematic child*, his *gender-salience filter* immediately makes gender highly relevant. Drawing on his prior learning, he asks himself, “Should boys play with dolls?” If he answers “yes” and the toy interests him, he will explore it and learn more about it. If he answers “no,” he will avoid the “gender-inappropriate” toy. But if Billy is a *gender-aschematic child*—one who seldom views the world in gender-linked terms—he simply asks himself, “Do I like this toy?” and responds on the basis of his interests.

Gender-schematic thinking is so powerful that when children see others behaving in “gender-inconsistent” ways, they often distort their memory to make it “gender-consistent.” For example, when shown a picture of a male nurse, they may remember him as a doctor (Martin & Ruble, 2004). And because gender-schematic preschoolers typically conclude, “What I like, children of my own sex will also like,” they often use their own preferences to add to their gender biases (Liben & Bigler, 2002). For example, a girl who dislikes oysters may declare, “Only boys like oysters!” even though she has never actually been given information promoting such a stereotype. At least partly for this reason, young children’s gender schemas contain both culturally

**FIGURE 8.3** Cognitive pathways for gender-schematic and gender-aschematic children. In *gender-schematic children*, the gender-salience filter immediately makes gender highly relevant: Billy sees a doll and thinks, “I’m a boy. Should boys play with dolls?” Drawing on his experiences, he answers “yes” or “no.” If he answers “yes” and the doll interests him, he plays with the doll. If he answers “no,” he avoids the “gender-inappropriate” toy. *Gender-aschematic children* rarely view the world in gender-linked terms: Billy simply asks, “Do I like this toy?” and responds on the basis of his interests. (Reprinted by permission of Rebecca Bigler.)

standard and nonstandard ideas (Tenenbaum et al., 2010). Not until well into the school years do children’s gender schemas fully resemble those of adults.

Gender identity involves self-perceptions that build on a core sense of one’s own gender. A few children, however, express great discomfort with the gender they were assigned at birth and want to live as the other gender, expressing this desire as early as the preschool years. For research on transgender children, refer to the Biology and Environment box on the following page.

## Reducing Gender Stereotyping in Young Children

How can we help young children avoid rigid gender schemas that restrict their behavior and learning opportunities? No easy recipe exists. Biology clearly affects children’s gender typing, channeling boys, on average, toward active, competitive play and girls toward quieter, more intimate interaction. At the same time, differential treatment of boys and girls begins as soon as they are born, amplifying biologically based tendencies and promoting a great many aspects of gender typing that are unrelated to human nature (Hines, 2015).

Because young children’s cognitive limitations lead them to assume that cultural practices determine gender, parents and teachers are wise to try to delay preschoolers’ exposure to gender-stereotyped messages. Adults can begin by limiting traditional gender roles in their own behavior and can provide children with nontraditional alternatives. For example, parents can take turns making dinner, bathing children, and driving the family car, and they can give their sons and daughters both trucks and dolls and both pink and blue clothing. Teachers can ensure that all children

spend time in mixed-gender play activities and unstructured pursuits, as children’s behavior tends to be less gender-typed in these contexts (Goble et al., 2012). Finally, adults can avoid using language that conveys gender stereotypes and can shield children from media presentations that do so.

Once children notice the vast array of gender stereotypes in their society, adults can point out exceptions. For example, they can arrange for children to see men and women pursuing nontraditional careers and can explain that interests and skills, not sex, should determine a person’s occupation. Research shows that such reasoning reduces children’s gender-biased views. By middle childhood, children who hold flexible beliefs about what boys and girls can do are more likely to notice instances of gender discrimination (Brown & Bigler, 2004). And as we will see next, a rational approach to child rearing promotes healthy, adaptable functioning in many other areas as well.

## Ask yourself

**CONNECT** In addition to gender-stereotyped beliefs, what other aspects of preschoolers’ social understanding tend to be rigid and one-sided?

**APPLY** List findings indicating that language and communication—between parents and children, between teachers and children, and between peers—powerfully affect children’s gender typing. What recommendations would you make to counteract these influences?

**REFLECT** Would you describe your own gender identity as “masculine,” “feminine,” or “androgynous”? What biological and social factors might have influenced your gender identity?

## Biology and Environment

### Transgender Children

Jacob, who began life as a girl named Mia, firmly insisted at age 2, “I am a boy!” in opposition to his parents’ suggestion that he was merely “pretending.” At preschool, he became increasingly angry at being identified as a girl. When his teacher asked him to write his name, he would print M-I-A but then vigorously cross it out. Gradually, his parents sensed the strength of his expressed identity. With guidance from a therapist, they began following his lead, providing boys’ clothes, a short haircut, superhero action figures, and toy cars. At age 4, after his parents presented him with several options, one of which was living as a boy, he affirmed that he wanted to change his name to Jacob and go to a different school, where he could start a new public life as a boy (Lemay, 2015). “I want to be a boy always,” Jacob declared. His problematic behavior at home and school quickly subsided.

The number of transgender children, adolescents, and adults in Western nations, though few, has risen recently—perhaps because more stories like Jacob’s are appearing in the media and because seeking treatment has become more acceptable. Individuals dissatisfied with their natal (birth) sex who strongly identify as the other sex experience substantial distress—a condition called *gender dysphoria*. Estimates based on large samples of Dutch and North American children suggest that about 1.5 percent of natal boys and 2 percent of natal girls suffer from gender dysphoria (Ristori & Steensma, 2016; Van Beijsterveldt, Hudziak, & Boomsma, 2006). Some researchers speculate that the sex difference has to do with greater cultural acceptance of gender nonconformity in girls, leading girls who experience gender dysphoria to express it more readily.

People who change gender in adulthood often trace the emergence of their gender dysphoria to early childhood. Although contributing factors are not well understood, the prenatal hormone environment seems to play a role. For example, genetic females known to have been exposed to high levels of prenatal androgens are more likely than other women

to be transgender (Dessens, Slijper, & Drop, 2005). But many females prenatally exposed to high androgen levels, and many males exposed to low levels, do not express discomfort with their natal sex.

Although some studies claim that most cases of childhood gender dysphoria subside in adolescence and adulthood, their samples failed to distinguish between gender-dysphoric children and children who merely display gender-nonconforming behavior. Children who are severely troubled over the mismatch between their natal sex and core gender identity, who insist that they are the other gender, and who also engage in high levels of “other-gender” behavior generally experience persisting dysphoria (Ristori & Steensma, 2016; Steensma et al., 2011). These persisters are likely to transition mostly or entirely—as Jacob did—to their desired gender role.

Transgender children are not pretending, confused, or delayed in gender understanding. When questioned about their peer preferences, gender-typed object choices, and gender identity, their responses are identical to those of nontransgender age-mates who share their expressed gender (Olson, Key, & Eaton, 2015).

During early adolescence, gender dysphoria typically deepens as persisters encounter changes in their bodies and first feelings of sexual attraction (Leibowitz & de Vries, 2016). Some desire, and may be deemed eligible for, psychological and medical sex-change treatment, involving suppression of pubertal sex hormones, cross-sex hormone treatment after age 16, and surgery after age 18. Others go through a period of questioning, including hesitancy over invasive treatments, and take additional time to assess their feelings about

COURTESY OF MIMI LEMAY

Jacob, who began life as a girl, changed his name and transitioned to living as a boy in early childhood. Transgender children whose parents support their desire to express their identified gender are more content and better-adjusted.

transitioning physically (Steensma & Cohen-Kettenis, 2015). A number of these young people find their gender dysphoria so overwhelming that they eventually decide on treatment in their twenties and thirties.

Controversy exists over therapies for gender-dysphoric children. One approach is directed at lessening their cross-gender identity and behavior and increasing their comfort with their natal sex. These therapies, however, have yielded poor results (Adelson, 2012; Byne et al., 2012). Gender-dysphoric children react with heightened distress to efforts to suppress or deny their identified gender.

Increasing numbers of health professionals are convinced that therapies must be aimed at permitting children to follow their gender-identity inclinations and helping parents protect their children from the negative reactions of others. These efforts are motivated by the tragic circumstances of many contemporary transgender adults, who experienced family rejection and social ostracism from childhood on and who face high rates of unemployment, poverty, homelessness, depression, and suicide (Byne et al., 2012; Di Ceglie, 2014; Haas, Rodgers, & Herman, 2014). Current evidence suggests that embracing transgender children’s expressed identity leads to contented, better-adjusted children and adolescents. Follow-up research is needed to assess long-term outcomes in the coming generation of transgender adults.

## Child Rearing and Emotional and Social Development

**8.9** Describe the impact of child-rearing styles on development, and explain why authoritative parenting is effective.

**8.10** Discuss the multiple origins of child maltreatment, its consequences for development, and prevention strategies.

In this and previous chapters, we have seen how parents can foster children's competence—by building a parent–child relationship based on affection and cooperation, by modeling mature behavior, by using reasoning and inductive discipline, and by guiding and encouraging mastery of new skills. Now let's put these practices together into an overall view of effective parenting.

### Styles of Child Rearing

**Child-rearing styles** are combinations of parenting behaviors that occur over a wide range of situations, creating an enduring child-rearing climate. In a landmark series of studies, Diana Baumrind (1971) gathered information on child rearing by watching parents interact with their preschoolers. Her findings, and those of others who have extended her work, reveal three features that consistently differentiate an effective style from less

effective ones: (1) acceptance and involvement, (2) control, and (3) autonomy granting (Gray & Steinberg, 1999; Hart, Newell, & Olsen, 2003). Table 8.2 shows how child-rearing styles differ in these features.

**Authoritative Child Rearing.** The **authoritative child-rearing style**—the most successful approach—involves high acceptance and involvement, adaptive control techniques, and appropriate autonomy granting. Authoritative parents are warm, attentive, and sensitive to their child's needs. They establish an enjoyable, emotionally fulfilling parent–child relationship that draws the child into close connection. At the same time, authoritative parents exercise firm, reasonable control. They insist on mature behavior, give reasons for their expectations, and use disciplinary encounters as “teaching moments” to promote the child's self-regulation. Finally, authoritative parents engage in gradual, appropriate autonomy granting, allowing the child to make decisions in areas where he is ready to do so (Baumrind, 2013; Kuczynski & Lollis, 2002; Russell, Mize, & Bissaker, 2004).

Throughout childhood and adolescence, authoritative parenting is linked to many aspects of competence—an upbeat mood, self-control, task persistence, cooperativeness, high self-esteem, social and moral maturity, and favorable school performance (Amato & Fowler, 2002; Aunola, Stattin, & Nurmi, 2000; Gonzalez & Wolters, 2006; Jaffe, Gullone, & Hughes, 2010; Mackey, Arnold, & Pratt, 2001; Milevsky et al., 2007).

**TABLE 8.2**  
Features of Child-Rearing Styles

CHILD-REARING STYLE	ACCEPTANCE AND INVOLVEMENT	CONTROL	AUTONOMY GRANTING
Authoritative	Is warm, responsive, attentive, and sensitive to the child's needs	Engages in adaptive behavioral control: Makes reasonable demands for mature behavior and consistently enforces and explains them	Permits the child to make decisions in accord with readiness Encourages the child to express thoughts, feelings, and desires When parent and child disagree, engages in joint decision making when possible
Authoritarian	Is cold and rejecting and frequently degrades the child	Engages in coercive behavioral control: Makes excessive demands for mature behavior, uses force and punishment Often uses psychological control, withdrawing love and intruding on the child's individuality and attachment to parents	Makes decisions for the child Rarely listens to the child's point of view
Permissive	Is warm but overindulgent or inattentive	Is lax in behavioral control: Makes few or no demands for mature behavior	Permits the child to make many decisions before the child is ready
Uninvolved	Is emotionally detached and withdrawn	Is lax in behavioral control: Makes few or no demands for mature behavior	Is indifferent to the child's decision making and point of view

**Authoritarian Child Rearing.** The **authoritarian child-rearing style** is low in acceptance and involvement, high in coercive control, and low in autonomy granting. Authoritarian parents appear cold and rejecting. To exert control, they yell, command, criticize, and threaten. “Do it because I said so!” is their attitude. They make decisions for their child and expect the child to accept their word unquestioningly. If the child resists, authoritarian parents resort to force and punishment.

Children of authoritarian parents are more likely to be anxious, unhappy, and low in self-esteem and self-reliance. When frustrated, they tend to react with hostility and, like their parents, use force to get their way. Boys, especially, show high rates of anger and defiance. Although girls also engage in acting-out behavior, they are more likely to be dependent, lacking interest in exploration, and overwhelmed by challenging tasks (Hart, Newell, & Olsen, 2003; Kakihara et al., 2010; Thompson, Hollis, & Richards, 2003). Children and adolescents exposed to the authoritarian style typically do poorly in school. However, because of their parents’ concern with control, they tend to achieve better and to commit fewer antisocial acts than peers with undemanding parents—that is, those whose parents use one of the two styles we will consider next (Steinberg, Blatt-Eisengart, & Cauffman, 2006).

In addition to unwarranted direct control, authoritarian parents engage in a more subtle type called **psychological control**, in which they attempt to take advantage of children’s psychological needs by intruding on and manipulating their verbal expressions, individuality, and attachments to parents. These parents frequently interrupt or put down the child’s ideas, decisions, and choice of friends. When they are dissatisfied, they withdraw love, making their affection contingent on the child’s compliance. Children subjected to psychological control exhibit adjustment problems involving both anxious, withdrawn behavior and defiance and aggression—especially the relational form, which (like parental psychological control) damages relationships through manipulation and exclusion (Barber, Stolz, & Olsen, 2005; Barber & Xia, 2013; Kuppens et al., 2013).

**Permissive Child Rearing.** The **permissive child-rearing style** is warm and accepting but uninvolved. Permissive parents are either overindulgent or inattentive and, thus, engage in little control. Instead of gradually granting autonomy, they allow children to make many of their own decisions at an age when they are not yet capable of doing so. Their children can eat meals and go to bed whenever they wish and can watch as much television as they want. They do not have to learn good manners or do any household chores. Although some permissive parents truly believe in this approach, many others simply lack confidence in their ability to influence their child’s behavior (Oyserman et al., 2005).

Children of permissive parents tend to be impulsive, disobedient, and rebellious. They are also overly demanding and dependent on adults, and they show less persistence on tasks, poorer

school achievement, and more antisocial behavior. The link between permissive parenting and dependent, nonachieving, rebellious behavior is especially strong for boys (Barber & Olsen, 1997; Steinberg, Blatt-Eisengart, & Cauffman, 2006).

**Uninvolved Child Rearing.** The **uninvolved child-rearing style** combines low acceptance and involvement with little control and general indifference to issues of autonomy. Often these parents are emotionally detached and depressed and so overwhelmed by life stress that they have little time and energy for children. At its extreme, uninvolved parenting is a form of child maltreatment called *neglect*. Especially when it begins early, it disrupts virtually all aspects of development (see Chapter 6, page 187). Even with less extreme parental disengagement, children and adolescents display many problems—poor emotional self-regulation, school achievement difficulties, depression, and antisocial behavior (Aunola, Stattin, & Nurmi, 2000; Schroeder et al., 2010).

## What Makes Authoritative Child Rearing Effective?

Like all correlational findings, the association between authoritative parenting and children’s competence is open to interpretation. Perhaps parents of well-adjusted children are authoritative because their youngsters have especially cooperative dispositions. But although temperamentally fearless, impulsive children and emotionally negative children are more likely to evoke coercive, inconsistent discipline, extra warmth and firm control succeed in modifying these children’s maladaptive styles (Cipriano & Stifter, 2010; Larzelere, Cox, & Mandara, 2013). With inhibited, fearful children, parents must suppress their tendency to overprotect their child. Instead, inhibited children benefit from extra encouragement to be assertive and express their autonomy (Nelson et al., 2006; Rubin & Burgess, 2002).

Longitudinal research indicates that among children of diverse temperaments, authoritative child rearing predicts maturity and adjustment into adolescence. The warmth and caring that authoritative parents accord their children are linked to favorable child functioning in many cultures and seem universally necessary (Khaleque & Rohner, 2002). And a variant of authoritative-ness in which parents exert strong control over the child’s behavior—becoming directive but not coercive—yields just as favorable long-term outcomes as a more democratic approach (Baumrind, Larzelere, & Owens, 2010). Indeed, some children, because of their dispositions, require “heavier doses” of certain authoritative features.

In sum, authoritative child rearing seems to create a positive emotional context for parental influence in the following ways:

- Warm, involved parents who are secure in the standards they hold for their children model caring concern as well as confident, self-controlled behavior.

- Children are far more likely to comply with and internalize control that appears fair and reasonable, not arbitrary.
- By adjusting demands and autonomy granting to children's capacities, authoritative parents convey to children that they are competent and can do things successfully for themselves. In this way, parents foster favorable self-esteem and cognitive and social maturity.
- Supportive aspects of the authoritative style, including parental acceptance, involvement, and rational control, are a powerful source of *resilience*, protecting children from the negative effects of family stress and poverty (Luthar, Crossman, & Small, 2015).

### LOOK and LISTEN

Ask several parents to explain their style of child rearing, inquiring about acceptance and involvement, control, and autonomy granting. Look, especially, for variations in amount and type of control over children's behavior along with parents' rationales.

## Cultural Variations

Although authoritative parenting is broadly advantageous, ethnic minority parents often have distinct child-rearing beliefs and practices that reflect cultural values. Let's look at some examples.

Compared with Western parents, Chinese parents describe their parenting as more controlling. They are more directive in teaching and scheduling their children's time, as a way of fostering self-control and high achievement. Chinese parents may appear less warm than Western parents because they withhold praise, which they believe results in self-satisfied, poorly motivated children (Cheah & Li, 2010; Ng, Pomerantz, & Deng, 2014). Chinese parents report expressing affection and concern and using induction and other reasoning-oriented discipline as much as American parents do, but they more often shame a misbehaving child, withdraw love, and use physical punishment (Cheah et al., 2009; Shwalb et al., 2004). When these practices become excessive, resulting in an authoritarian style high in psychological or coercive control, Chinese children display the same negative outcomes as Western children: poor academic achievement, anxiety, depression, impaired self-regulation, and aggressive behavior (Chan, 2010; Lee et al., 2012; Pong, Johnston, & Chen, 2010; Sorkhabi & Mandara, 2013).

In Hispanic families, Asian Pacific Island families, and Caribbean families of African or East Indian origin, firm insistence on respect for parental authority is paired with high parental warmth—a combination suited to promoting cognitive and social competence and family loyalty (Roopnarine & Evans, 2007; Tamis-LeMonda & McFadden, 2010). Hispanic fathers

© JANINE WIEDEL PHOTOGRAPHY/ALAMY

In Caribbean families of African origins, respect for parental authority is paired with high parental warmth—a combination that promotes competence and family loyalty.

typically spend much time with their children and are warm and sensitive (Cabrera & Bradley, 2012).

Although wide variation exists, low-SES African-American parents tend to expect immediate obedience. They believe that strict parenting fosters self-control and vigilance in risky surroundings. African-American parents who use controlling strategies tend to have cognitively and socially competent children who view parental control as a sign of love and concern. And among African-American youths, controlling parenting protects against delinquency and disruptive behaviors at school (Mason et al., 2004; Roche, Ensminger, & Cherlin, 2007). Recall, also, that a history of mild physical punishment is not associated with behavior problems among African-American children (refer to the Cultural Influences box on page 270). Most African-American parents who use strict, “no-nonsense” discipline use physical punishment sparingly and combine it with warmth and reasoning.

These cultural variations remind us that child-rearing styles must be viewed in their larger contexts. As we have seen, many factors contribute to good parenting: personal characteristics of both child and parent, SES, access to extended family and community supports, cultural values and practices, and public policies.

As we turn to the topic of child maltreatment, our discussion will underscore, once again, that effective child rearing is sustained not just by the desire of mothers and fathers to be good parents. Almost all want to be. Unfortunately, when vital supports for parenting break down, children—as well as parents—can suffer terribly.

## Child Maltreatment

Child maltreatment is as old as human history, but only in recent decades has the problem been widely acknowledged and studied. Perhaps public concern has increased because child maltreatment is especially common in large industrialized nations. In the most recently reported year, about 680,000 U.S. children (9 out of every 1,000) were identified as victims (U.S. Department of Health and Human Services, 2015c). Because most cases go unreported, the true figures are much higher.

Child maltreatment takes the following forms:

- **Physical abuse:** Assaults, such as kicking, biting, shaking, punching, or stabbing, that inflict physical injury
- **Sexual abuse:** Fondling, intercourse, exhibitionism, commercial exploitation through prostitution or production of pornography, and other forms of sexual exploitation
- **Neglect:** Failure to meet a child's basic needs for food, clothing, medical attention, education, or supervision
- **Emotional abuse:** Acts that could cause serious emotional harm, including social isolation, repeated unreasonable demands, ridicule, humiliation, intimidation, or terrorizing

Neglect accounts for about 80 percent of reported cases, physical abuse for 18 percent, emotional abuse for 9 percent, and sexual abuse for 9 percent (U.S. Department of Health and Human Services, 2015c). But these figures are only approximate, as many children experience more than one form.

Parents commit more than 80 percent of abusive incidents. Other relatives account for about 5 percent, and the remainder are perpetrated by parents' unmarried partners, child-care providers, and other adults. Infants, toddlers, and preschoolers are at greatest risk for neglect, physical abuse, and emotional abuse. Sexual abuse is perpetrated more often against school-age and early adolescent children. But each type occurs at every age (Trocmé & Wolfe, 2002; U.S. Department of Health and Human Services, 2015c). Because many sexual abuse victims are identified in middle childhood, we will pay special attention to this form of maltreatment in Chapter 10.

**Origins of Child Maltreatment.** Early findings suggested that child maltreatment was rooted in adult psychological disturbance (Kempe et al., 1962). But although child maltreatment is more common among disturbed parents, it soon became clear that a single “abusive personality type” does not exist. Parents who were abused as children do not necessarily become abusers (Jaffee et al., 2013). And sometimes even “normal” parents harm their children.

For help in understanding child maltreatment, researchers turned to *ecological systems theory* (see Chapters 1 and 2). They discovered that many interacting variables—at the family, community, and cultural levels—contribute. The more risks present, the greater the likelihood of abuse or neglect (see Table 8.3).

**The Family.** Within the family, children whose characteristics make them more challenging to rear are more likely to become targets of abuse. These include premature or very sick babies and children who are temperamentally difficult, are inattentive and overactive, or have other developmental problems. Child factors, however, only slightly increase the risk of abuse (Jaudes & Mackey-Bilaver, 2008; Sidebotham et al., 2003). Whether such children are maltreated largely depends on parents' characteristics.

**TABLE 8.3**  
**Factors Related to Child Maltreatment**

FACTOR	DESCRIPTION
Parent characteristics	Psychological disturbance; alcohol and drug abuse; history of abuse as a child; belief in harsh physical discipline; desire to satisfy unmet emotional needs through the child; unreasonable expectations for child behavior; young age (most under 30); low educational level; lack of parenting skills
Child characteristics	Premature or very sick baby; difficult temperament; inattentiveness and overactivity; other developmental problems
Family characteristics	Low income or poverty; homelessness; marital instability; social isolation; partner abuse; frequent moves; large families with closely spaced children; overcrowded living conditions; presence of nonbiological caregivers; disorganized household; lack of steady employment; other signs of high life stress
Community	Characterized by violence and social isolation; few parks, child-care centers, preschool programs, recreation centers, or religious institutions to serve as family supports
Culture	Approval of physical force and violence as ways to solve problems

Sources: Centers for Disease Control and Prevention, 2015c; Wekerle & Wolfe, 2003; Whipple, 2006.

© JEFF GREENBERG/PHOTOEDIT

High parental stress, low income and education, and extreme household disorganization are often associated with child maltreatment. Abusive parents are more likely to live in rundown neighborhoods that offer few sources of social support.

Maltreating parents are less skillful than other parents in handling discipline confrontations. They also suffer from biased thinking about their child. For example, they often attribute their baby's crying or their child's misdeeds to a stubborn or bad disposition, evaluate children's transgressions as worse than they are, and feel powerless in parenting—perspectives that lead them to move quickly toward physical force (Bugental & Happaney, 2004; Crouch et al., 2008).

Most parents have enough self-control not to respond with abuse to their child's misbehavior or developmental problems. Other factors combine with these conditions to prompt an extreme response. Abusive parents react to stressful situations with high emotional arousal. And low income, low education (less than a high school diploma), unemployment, alcohol and drug use, marital conflict, overcrowded living conditions, frequent moves, and extreme household disorganization are common in abusive and neglectful homes (Dakil et al., 2012; Wulczyn, 2009). These conditions increase the chances that parents will be too overwhelmed to meet basic child-rearing responsibilities or will vent their frustrations by lashing out at their children.

**The Community.** The majority of abusive and neglectful parents are isolated from both formal and informal social supports. Because of their life histories, many have learned to mistrust and avoid others and are poorly skilled at establishing and maintaining positive relationships. Also, maltreating parents are more likely to live in unstable, rundown neighborhoods that provide few links between family and community, such as parks, recreation centers, and religious institutions (Guterman

et al., 2009; Tomyr, Ouimet, & Ugnat, 2012). They lack “lifelines” to others and have no one to turn to for help during stressful times.

**The Larger Culture.** Cultural values, laws, and customs profoundly affect the chances that child maltreatment will occur when parents feel overburdened. Societies that view violence as an appropriate way to solve problems set the stage for child abuse.

Although the United States has laws to protect children from maltreatment, widespread support exists for use of physical force with children (refer back to page 269). Twenty-three European countries have outlawed corporal punishment, a measure that dampens both physical discipline and abuse (duRivage et al., 2015; Zolotor & Puzia, 2010). Furthermore, all industrialized nations except the United States prohibit corporal punishment in schools. The U.S. Supreme Court has twice upheld the right of school officials to use corporal punishment. Fortunately, 31 U.S. states and the District of Columbia have passed laws that ban it.

**Consequences of Child Maltreatment.** The family circumstances of maltreated children impair the development of emotional self-regulation, empathy and sympathy, self-concept, social skills, and academic motivation. Over time, these youngsters show serious adjustment problems—cognitive deficits including impaired executive function, school failure, deficits in processing emotional and social signals, peer difficulties, severe depression, aggressive behavior, substance abuse, and violent crime (Cicchetti & Toth, 2015; Nikulina & Widom, 2013; Stronach et al., 2011).

How do these damaging consequences occur? Recall our earlier discussion of hostile cycles of parent–child interaction. For abused children, these are especially severe. Also, a family characteristic strongly associated with child abuse is partner abuse (Graham-Bermann & Howell, 2011). Clearly, the home lives of abused children overflow with adult conduct that leads to profound distress and to use of aggression to solve problems.

Furthermore, the sense of abandonment conveyed by neglectful parenting and the humiliating, terrorizing behaviors of abusive adults result in low self-esteem, high anxiety, self-blame, and efforts to escape from extreme psychological pain—at times severe enough to lead to post-traumatic stress disorder (PTSD) and attempted suicide in adolescence. At school, maltreated children present serious discipline problems (Nikulina, Widom, & Czaja, 2011; Wolfe, 2005). Their noncompliance, poor motivation, and cognitive immaturity interfere with academic achievement, further undermining their chances for life success.

Finally, chronic abuse is associated with central nervous system damage, including abnormal EEG brain-wave activity; fMRI-detected reduced size and impaired functioning of the

cerebral cortex, corpus callosum, cerebellum, and hippocampus; and atypical production of the stress hormone cortisol—initially too high but, after months of abuse, often too low. Over time, the massive trauma of persistent abuse seems to blunt children’s normal physiological response to stress (Cicchetti & Toth, 2015; Jaffee & Christian, 2014). These effects increase the chances that cognitive and emotional problems will endure.

**Preventing Child Maltreatment.** Because child maltreatment is embedded in families, communities, and society as a whole, efforts to prevent it must be directed at each of these levels. Many approaches have been suggested, from teaching high-risk parents effective child-rearing strategies to developing broad social programs aimed at improving economic conditions and community services.

Each year, fourth to sixth graders across Los Angeles County enter a poster contest to celebrate Child Abuse Prevention Month. This recent winner urges parents not to commit acts of physical and emotional abuse. (Jonathan Chin, 10th Grade, Yaya Fine Art Studio, Temple City, CA. Courtesy ICAN Associates, Los Angeles County Inter-Agency Council on Child Abuse and Neglect, [ican4kids.org](http://ican4kids.org).)

We have seen that providing social supports to families is effective in easing parental stress. This approach sharply reduces child maltreatment as well. Parents Anonymous, a U.S. organization with affiliate programs around the world, helps child-abusing parents learn constructive parenting practices, largely through social supports. Its local chapters offer self-help group meetings, daily phone calls, and regular home visits to relieve social isolation and teach child-rearing skills.

Early intervention aimed at strengthening both child and parent competencies can prevent child maltreatment. Healthy Families America, a program that began in Hawaii and has spread to 430 sites across the United States and Canada, identifies families at risk for maltreatment during pregnancy or at birth. Each receives three years of home visitation, in which a trained worker helps parents manage crises, encourages effective child rearing, and puts parents in touch with community services (Healthy Families America, 2011). In evaluations of sites verified to provide high-quality program delivery, parents randomly assigned to Healthy Families home visitation, compared with no-intervention controls, more often engaged their child in developmentally supportive activities and used effective discipline strategies; less often displayed harsh, coercive tactics; and reported less parenting stress—factors that reduce the risk of child maltreatment (Green et al., 2014; LeCroy & Krysik, 2011). Another home-visiting program that prevents child abuse and neglect is the Nurse–Family Partnership, discussed on page 90 in Chapter 3 (Olds et al., 2009).

Even with intensive treatment, some adults persist in their abusive acts. An estimated 1,600 U.S. children, most of them infants and preschoolers, die from maltreatment annually (U.S. Department of Health and Human Services, 2015c). When parents are unlikely to change their behavior, the drastic step of separating parent from child and legally terminating parental rights is the only justifiable course of action.

Child maltreatment is a sad note on which to end our discussion of a period of childhood that is so full of excitement, awakening, and discovery. But there is reason to be optimistic. Great strides have been made over the past several decades in understanding and preventing child maltreatment.

## Ask yourself

**CONNECT** Which child-rearing style is most likely to be associated with inductive discipline, and why?

**APPLY** Chandra heard a news report about 10 severely neglected children, living in squalor in an inner-city tenement. She wondered, “Why would parents so mistreat their children?” How would you answer Chandra?

**REFLECT** How would you classify your parents’ child-rearing styles? What factors might have influenced their approach to parenting?

## Summary / chapter 8

### Erikson's Theory: Initiative versus Guilt (p. 258)

#### 8.1 What personality changes take place during Erikson's stage of initiative versus guilt?

- Preschoolers develop a new sense of purposefulness as they grapple with Erikson's psychological conflict of **initiative versus guilt**. A healthy sense of initiative depends on exploring the social world through play, cooperating with peers to achieve common goals, and forming a conscience through identification with the same-sex parent.

© ALVARO LEIVA/ROBERT HARDING WORLD IMAGERY

### Self-Understanding (p. 258)

#### 8.2 Describe the development of self-concept and self-esteem in early childhood.

- As preschoolers think more intently about themselves, they construct a **self-concept** consisting largely of observable characteristics and typical emotions and attitudes. A warm, sensitive parent-child relationship fosters a more positive, coherent early self-concept.
- Preschoolers' high **self-esteem** consists of several self-judgments and contributes to a mastery-oriented approach to the environment.

### Emotional Development (p. 260)

#### 8.3 Identify changes in understanding and expressing emotion during early childhood, citing factors that influence those changes.

- Preschoolers' impressive understanding of the causes, consequences, and behavioral signs of basic emotions is supported by cognitive and language development, secure attachment, and conversations about feelings.

- By age 3 to 4, children are aware of various strategies for emotional self-regulation. Temperament, parental modeling, and parental communication about coping strategies influence preschoolers' capacity to handle stress and negative emotion.
- As their self-concepts develop, preschoolers more often experience self-conscious emotions. They depend on feedback from parents and other adults to know when to feel these emotions.
- Empathy also becomes more common in early childhood. The extent to which empathy leads to **sympathy** and results in **prosocial**, or **altruistic**, behavior depends on temperament and parenting.

### Peer Relations (p. 263)

#### 8.4 Describe peer sociability and friendship in early childhood, along with cultural and parental influences on early peer relations.

- During early childhood, peer interaction increases as children move from **nonsocial activity** to **parallel play**, then to **associative** and **cooperative play**. Nevertheless, both solitary and parallel play remain common.
- Sociodramatic play seems especially important in societies where child and adult worlds are distinct. In collectivist cultures, play generally occurs in large groups and is highly cooperative.
- Interactions between preschool friends are unusually positive, but friendship does not yet have an enduring quality based on mutual trust. Early childhood social competence contributes to later academic performance.
- Parents affect peer sociability both directly, by influencing their child's peer relations, and indirectly, through their child-rearing practices.

### Foundations of Morality and Aggression (p. 267)

#### 8.5 What are the central features of psychoanalytic, social learning, and cognitive-developmental approaches to moral development?

- The psychoanalytic perspective stresses the emotional side of conscience development, especially identification and guilt as motivators of moral action. But contrary to Freud's view that morality develops out of fear of punishment and loss of parental love, conscience formation is promoted by **induction**, in which adults point out the effects of the child's misbehavior on others.

- Social learning theory focuses on how moral behavior is learned through modeling by warm, powerful, and consistent adults. Giving children material rewards undermines prosocial behavior.
- Alternatives to harsh punishment such as **time out** and withdrawal of privileges can help parents avoid undesirable side effects of punishment. Parents can increase the effectiveness of mild punishment by being consistent, maintaining a warm parent-child relationship, and offering explanations.
- The cognitive-developmental perspective views children as active thinkers about social rules. By age 4, children consider intentions in making moral judgments and distinguish truthfulness from lying. Preschoolers also distinguish **moral imperatives** from **social conventions** and **matters of personal choice**. However, they tend to reason rigidly about morality, focusing on outcomes and on physical harm.

© JEFF GREENBERG/PHOTODEBIT

#### 8.6 Describe the development of aggression in early childhood, including family and media influences and effective approaches to reducing aggressive behavior.

- During early childhood, **proactive aggression** declines while **reactive aggression** increases. Proactive and reactive aggression come in three forms: **physical aggression** (more common in boys), **verbal aggression**, and **relational aggression**.
- Ineffective discipline and a conflict-ridden family atmosphere promote children's aggression, as does media violence. Effective approaches to reducing aggressive behavior include training parents in effective child-rearing practices, teaching children conflict-resolution skills, helping parents cope with stressors in their own lives, and shielding children from violent media.

## Gender Typing (p. 276)

### 8.7 Discuss biological and environmental influences on preschoolers' gender-stereotyped beliefs and behavior.

- **Gender typing** is well under way in early childhood. Preschoolers acquire a wide range of gender-stereotyped beliefs, often applying them rigidly.

© LAURA DWIGHT PHOTOGRAPHY

- Prenatal hormones contribute to boys' higher activity level and rougher play and to children's preference for same-sex playmates. But parents, teachers, peers, and the broader social environment also encourage many gender-typed responses.

### 8.8 Describe and evaluate major theories that explain the emergence of gender identity.

- Although most people have a traditional **gender identity**, some are **androgynous**, combining both masculine and feminine characteristics. Masculine and androgynous identities are linked to better psychological adjustment.

- According to social learning theory, preschoolers first acquire gender-typed responses through modeling and reinforcement and then organize these behaviors into gender-linked ideas about themselves. Cognitive-developmental theory suggests that children must master **gender constancy** before developing gender-typed behavior, but evidence for this assumption is weak.
- **Gender schema theory** combines features of social learning and cognitive-developmental perspectives. As children acquire gender-typed preferences and behaviors, they form masculine and feminine categories, or gender schemas, that they apply to themselves and their world.
- A few children express great discomfort with the gender they were assigned at birth and, as early as the preschool years, express a desire to live as the other gender.

## Child Rearing and Emotional and Social Development (p. 282)

### 8.9 Describe the impact of child-rearing styles on development, and explain why authoritative parenting is effective.

- Three features distinguish **child-rearing styles**: degree of (1) acceptance and involvement, (2) control, and (3) autonomy granting. Compared with the **authoritarian**, **permissive**, and **uninvolved** styles, the **authoritative style** promotes cognitive, emotional, and social competence. Warmth, reasonable rather than coercive control, and gradual autonomy granting account for the effectiveness of this style. **Psychological control**, which is associated with authoritarian parenting, contributes to adjustment problems.

- Although some ethnic groups effectively combine parental warmth with high levels of control, harsh and excessive control impairs academic and social competence.

© JANINE WIEDEL PHOTOLIBRARY/ALAMY

### 8.10 Discuss the multiple origins of child maltreatment, its consequences for development, and prevention strategies.

- Maltreating parents use ineffective discipline, hold a negatively biased view of their child, and feel powerless in parenting. Unmanageable parental stress and social isolation greatly increase the likelihood of abuse and neglect. Societal approval of corporal punishment promotes child abuse.
- Maltreated children are impaired in emotional self-regulation, empathy and sympathy, self-concept, social skills, and academic motivation. The trauma of repeated abuse is associated with central nervous system damage and serious, lasting adjustment problems. Successful prevention requires efforts at the family, community, and societal levels.

## Development in Early Childhood

D. HURST/ALAMY

### 2 YEARS

#### Physical

- Throughout early childhood, height and weight increase more slowly than in toddlerhood. (216)
- Balance improves; walks more rhythmically; hurried walk changes to run. (223)
- Jumps, hops, throws, and catches with rigid upper body. (223)
- Puts on and removes simple items of clothing. (223)
- Uses spoon effectively. (223)
- First drawings are gestural scribbles. (224)

#### Cognitive

- Make-believe becomes less dependent on realistic objects, less self-centered, and more complex; sociodramatic play increases. (228)
- Understands the symbolic function of photos and realistic-looking pictures. (229)
- Takes the perspective of others in simplified, familiar situations and in face-to-face communication. (231, 252)
- Recognition memory is well-developed. (239)
- Shows awareness of the distinction between inner mental and outer physical events. (241)
- Attaches verbal labels to amounts and sizes; begins to count. (244)

PEOPLEIMAGES.COM/GETTY IMAGES

#### Language

- Vocabulary increases rapidly. (250)
- Uses a coalition of cues—perceptual and, increasingly, social and linguistic—to figure out word meanings. (250–251)
- Speaks in simple sentences that follow basic word order of native language, gradually adding grammatical markers. (251)
- Displays effective conversational skills. (252)

#### Emotional/Social

- Understands causes, consequences, and behavioral signs of basic emotions. (260)

ELLEN B. SENISI PHOTOGRAPHY

- Begins to develop self-concept and self-esteem. (258–260)
- Shows early signs of developing moral sense—verbal evaluations of own and others' actions and distress at harmful behaviors. (267)
- May display proactive (instrumental) aggression. (272–273)
- Gender-stereotyped beliefs and behavior increase. (276)

### 3–4 YEARS

#### Physical

- Running, jumping, hopping, throwing, and catching become better coordinated. (223)
- Pedals and steers tricycle. (223)

LAURA DWIGHT PHOTOGRAPHY

- Galloping and one-foot skipping appear. (223)
- Fastens and unfastens large buttons. (223)
- Uses scissors. (223)
- Uses fork effectively. (223)
- Draws first picture of a person, using tadpole image. (224)

#### Cognitive

- Understands the symbolic function of drawings and of models of real-world spaces. (224, 228–229)
- Grasps conservation, reasons about transformations, reverses thinking, and understands cause–effect sequences in simplified, familiar situations. (231–233)
- Sorts familiar objects into hierarchically organized categories. (232)
- Uses private speech to guide behavior during challenging tasks. (234–235)
- Gains in executive function, including inhibition, flexible shifting of attention, and working memory capacity. (236–238)
- Uses scripts to recall routine events. (240)
- Understands that both beliefs and desires determine behavior. (241)
- Knows the meaning of numbers up to 10, counts correctly, and grasps cardinality. (244)

Note: Numbers in parentheses indicate the page or pages on which each milestone is discussed.

## Language

- Aware of some meaningful features of written language. (244)

- Coins new words based on known words; extends language meanings through metaphor. (250)
- Masters increasingly complex grammatical structures, occasionally overextending grammatical rules to exceptions. (251–252)
- Adjusts speech to fit the age, sex, and social status of listeners. (252)

## Emotional/Social

- Describes self in terms of observable characteristics and typical emotions and attitudes. (258–259)
- Has several self-esteems, such as learning things in school, making friends, getting along with parents, and treating others kindly. (260)
- Emotional self-regulation improves. (261)
- Experiences self-conscious emotions more often. (262)
- Relies more on language to express empathy. (262)
- Proactive aggression declines, while reactive aggression (verbal and relational) increases. (272–273)
- Engages in associative and cooperative play with peers, in addition to parallel play. (263)

- Forms first friendships, based on pleasurable play and sharing of toys. (265)
- Distinguishes truthfulness from lying. (271)
- Distinguishes moral imperatives from social conventions and matters of personal choice. (272)
- Preference for same-sex playmates strengthens. (277)

## 5–6 YEARS

## Physical

- Starts to lose primary teeth. (217)
- Increases running speed, gallops more smoothly, and engages in true skipping. (223)
- Displays mature, flexible throwing and catching patterns. (223)
- Uses knife to cut soft foods. (223)
- Ties shoes. (223, 224)
- Draws more complex pictures. (224)

- Copies some numbers and simple words; prints name. (223, 225)

## Cognitive

- Magical beliefs decline. (231)
- Improves in ability to distinguish appearance from reality. (228)
- Gains further in executive function, including planning. (237–238)

- Improves in recognition, recall, scripted memory, and autobiographical memory. (239–240)
- Understanding of false belief strengthens. (241)

## Language

- Understands that letters and sounds are linked in systematic ways. (244)
- Uses invented spellings. (244)
- By age 6, has acquired a vocabulary of about 10,000 words. (250)
- Uses most grammatical constructions competently. (251)

## Emotional/Social

- Improves in emotional understanding, including the ability to interpret, predict, and influence others' emotional reactions. (260–261)

- Has acquired many morally relevant rules and behaviors. (268)
- Gender-stereotyped beliefs and behavior and preference for same-sex playmates continue to strengthen. (277)
- Understands gender constancy. (279)

## Physical and Cognitive Development in Middle Childhood

During a first grade math activity, students work together to take measurements and record data. An improved capacity to remember, reason, and reflect on one's thinking makes middle childhood a time of dramatic advances in academic learning and problem solving.

“I’m on my way, Mom!” hollered 10-year-old Joey as he stuffed the last bite of toast into his mouth, slung his book bag over his shoulder, dashed out the door, jumped on his bike, and headed down the street for school. Joey’s 8-year-old sister Lizzie followed, pedaling furiously until she caught up with Joey. Rena, the children’s mother and one of my colleagues at the university, watched from the front porch as her son and daughter disappeared in the distance.

“They’re branching out,” Rena commented to me over lunch that day as she described the children’s expanding activities and relationships. Homework, household chores, soccer teams, music lessons, scouting, friends at school and in the neighborhood, and Joey’s new paper route were all part of the children’s routine. “It seems the basics are all there. I don’t have to monitor Joey and Lizzie so constantly anymore. Being a parent is still challenging, but it’s more a matter of refinements—helping them become independent, competent, and productive individuals.”

Joey and Lizzie have entered middle childhood—the years from 6 to 11. Around the world, children of this age are assigned new responsibilities. For children in industrialized nations, middle childhood is often called the “school years” because its onset is marked by the start of formal schooling. In village and tribal cultures, the school may be a field or a jungle. But universally, mature members of society guide children of this age period toward real-world tasks that increasingly resemble those they will perform as adults.

This chapter focuses on physical and cognitive development in middle childhood. By age 6, the brain has reached 90 percent of its adult weight, and the body continues to grow slowly. In this way, nature gives school-age children the mental powers to master challenging tasks as well as added time—before reaching physical maturity—to acquire fundamental knowledge and skills for life in a complex social world.

We begin by reviewing typical growth trends, gains in motor skills, and special health concerns. Then we return to Piaget’s theory and the information-processing approach for an overview of cognitive changes. Next, we examine genetic and environmental contributions to IQ scores, which often influence important educational decisions. Our discussion continues with the further blossoming of language. Finally, we consider the role of schools in children’s learning and development. ●

## PHYSICAL DEVELOPMENT

### Body Growth

#### 9.1 Describe major trends in body growth during middle childhood.

Physical growth during the school years continues at the slow, regular pace of early childhood. At age 6, the average North American child weighs about 45 pounds and is 3½ feet tall. Over the next few years, children will add about 2 to 3 inches in height and 5 pounds in weight each year (see Figure 9.1). Between ages 6 and 8, girls are slightly shorter and lighter than boys. By age 9, this trend reverses as girls approach the dramatic adolescent growth spurt, which occurs two years earlier in girls than in boys.

Because the lower portion of the body is growing fastest, Joey and Lizzie appeared longer-legged than they had in early

childhood. They grew out of their jeans more quickly than their jackets and frequently needed larger shoes. As in early childhood, girls have slightly more body fat and boys more muscle. After age 8, girls begin accumulating fat at a faster rate, and they will add even more during adolescence (Hauspie & Roelants, 2012).

During middle childhood, the bones of the body lengthen and broaden. However, ligaments are not yet firmly attached to bones. This, combined with increasing muscle strength, gives children the unusual flexibility needed to perform cartwheels and handstands. As their bodies become stronger, many children experience a greater desire for physical exercise. Nighttime “growing pains”—stiffness and aches in the legs—are common as muscles adapt to an enlarging skeleton (Uziel et al., 2012).

Between ages 6 and 12, all 20 primary teeth are lost and replaced by permanent ones, with girls losing their teeth slightly earlier than boys. For a while, the permanent teeth seem much too large. Gradually, growth of facial bones causes the child’s face to lengthen and mouth to widen, accommodating the newly erupting teeth.

**FIGURE 9.1** Body growth during middle childhood. Mai and Henry continue to display the slow, regular pattern of growth they showed in early childhood. Around age 9, girls begin to grow at a faster rate than boys as the adolescent growth spurt draws near.

## Common Health Problems

- 9.2** Describe the causes and consequences of serious nutritional problems in middle childhood, giving special attention to obesity.
- 9.3** What vision and hearing problems are common in middle childhood?
- 9.4** What factors contribute to illness during the school years, and how can these health problems be reduced?
- 9.5** Describe changes in the occurrence of unintentional injuries in middle childhood, and cite effective interventions.

Children from economically advantaged homes, like Joey and Lizzie, are at their healthiest in middle childhood, full of energy and play. Growth in lung size permits more air to be exchanged with each breath, so children are better able to exercise vigorously without tiring. The cumulative effects of good nutrition, combined with rapid development of the body's immune system, offer greater protection against disease.

Not surprisingly, poverty continues to be a powerful predictor of ill health during middle childhood. Because economically disadvantaged U.S. families often lack health insurance (see Chapter 7), many children do not have regular access to a doctor. A substantial number also lack such basic necessities as a comfortable home and regular meals.

### Nutrition

Children need a well-balanced, plentiful diet to provide energy for successful learning in school and increased physical activity. With their increasing focus on friendships and new activities, many children spend little time at the table, and the number who eat dinner with their families drops sharply between ages 9 and 14. Family dinnertimes have waned in general, yet eating an evening meal with parents leads to a diet higher in fruits, vegetables, grains, and milk products and lower in soft drinks and fast foods (Burgess-Champoux et al., 2009; Hammons & Fiese, 2011).

School-age children report that they “feel better” and “focus better” after eating healthy foods and that they feel sluggish, “like a blob,” after eating junk foods. In a longitudinal study of nearly 14,000 U.S. children, a parent-reported diet high in sugar, fat, and processed food in early childhood predicted slightly lower IQ at age 8, after many factors that might otherwise account for this association were controlled (Northstone et al., 2012). Even mild nutritional deficits can affect cognitive functioning. Among school-age children from middle- to high-SES families, insufficient dietary iron and folate are related to poorer concentration and mental test performance (Arija et al., 2006; Low et al., 2013).

As we saw in earlier chapters, many poverty-stricken children in developing countries and in the United States suffer from serious and prolonged malnutrition. Unfortunately, malnutrition that persists from infancy or early childhood into the school years usually results in permanent physical and mental damage

(Grantham-McGregor, Walker, & Chang, 2000; Liu et al., 2003). Government-sponsored supplementary food programs from the early years through adolescence can prevent these effects.

### Overweight and Obesity

Mona, a very heavy child in Lizzie's class, often watched from the sidelines during recess. When she did join in games, she was slow and clumsy, the target of unkind comments: “Move it, Tubs!” Most afternoons, she walked home from school alone while her schoolmates gathered in groups, talking, laughing, and chasing. At home, Mona sought comfort in high-calorie snacks.

Mona suffers from **obesity**, a greater-than-20-percent increase over healthy weight, based on *body mass index (BMI)*—a ratio of weight to height associated with body fat. A BMI above the 85th percentile for a child's age and sex is considered *overweight*, a BMI above the 95th percentile *obese*. During the past several decades, a rise in overweight and obesity has occurred in many Western nations, with large increases in Canada, Germany, Greece, Ireland, Israel, New Zealand, the United Kingdom, and the United States. Since the 1970s, U.S. childhood obesity has tripled. Today, 32 percent of U.S. children and adolescents are overweight, more than half of them extremely so: 17 percent are obese (Ogden et al., 2014; World Health Organization, 2015g).

Obesity rates have also risen in developing countries, as urbanization shifts the population toward sedentary lifestyles and diets high in meats and energy-dense refined foods (World Health Organization, 2015g). In China, for example, where obesity was nearly nonexistent a generation ago, today 20 percent of children are overweight and 8 percent obese, with two to three times as many boys as girls affected (Sun et al., 2014). In addition to lifestyle changes, a prevailing belief in Chinese culture that excess body fat signifies prosperity and health—carried over from a half-century ago, when famine caused millions of deaths—has contributed to this alarming upsurge. High valuing of sons may induce Chinese parents to offer boys especially generous portions of energy-dense foods.

Overweight rises with age, from 23 percent among U.S. preschoolers to 35 percent among school-age children and adolescents to an astronomical 69 percent among adults (Ogden et al., 2014). Overweight preschoolers are five times more likely than their normal-weight peers to be overweight at age 12, and few persistently overweight adolescents attain a normal weight in adulthood (Nader et al., 2006; Patton et al., 2011).

**Causes of Obesity.** Not all children are equally at risk for excessive weight gain. Identical twins are more likely than fraternal twins to resemble each other in BMI, and adopted children tend to resemble their biological parents (Min, Chiu, & Wang, 2013). Although heredity clearly contributes to children's risk, the importance of environment is apparent in the consistent relationship of low SES to overweight and obesity in industrialized nations, especially among ethnic minorities—in the United States, African-American, Hispanic, and Native-American

## Social Issues: Health

### Family Stressors and Childhood Obesity

In response to chronic stress, many adults and children increase their food consumption—especially foods high in sugar and fat—and gain excessive weight. How can a stressful daily life prompt overeating?

One route is through elevated stress hormones, including cortisol, which signal the body to increase energy expenditure and the brain, in turn, to boost caloric intake (Zellner et al., 2006). In a second pathway, chronic stress triggers insulin resistance—a pre-diabetic condition that frequently induces a raging appetite (Dallman et al., 2003).

Furthermore, the effort required to manage persistent stress can easily strain self-regulatory capacity, leaving the individual unable to limit excessive eating. Deficits in inhibition and a related capacity, delay of gratification (ability to wait for a reward), are associated with childhood obesity (Liang et al., 2014). And in several studies, the greater the number of home-life stressors in school-age children's lives, the poorer their regulation of negative emotion and behavior (Evans, 2003; Evans et al., 2005). Impaired self-regulation,

then, might be a major intervening factor in the link between childhood chronic stress and obesity. To find out, researchers followed several hundred children from economically disadvantaged families, assessing family stressors and self-regulatory ability at age 9 and change in BMI four years later, at age 13 (Evans et al., 2012). Number of stressors experienced—including poverty, single-parent household, residential crowding, noise, household clutter, lack of books and play materials, child separation from the family, and exposure to violence—strongly predicted impaired self-regulation, as indicated by children's delay of gratification. Poor self-regulation, in turn, largely accounted for the relationship between family stressors and gain in BMI over time.

In obesity prevention programs, children given self-regulation training—instructions to “stop and think” in eating situations—show

beneficial outcomes in terms of improved eating behaviors and weight control (Johnson, 2000). But such training is likely to be fully effective only when stressors in children's family lives are manageable, not overwhelming.

children and adults (Ogden et al., 2014). Factors responsible include lack of knowledge about healthy diet; a tendency to buy high-fat, low-cost foods; and family stress, which can prompt overeating. Recall, also, that children who were undernourished in their early years are at risk for later excessive weight gain (see page 129 in Chapter 4).

Parental feeding practices also contribute to childhood obesity. Overweight children are more likely to eat sugary and fatty foods, perhaps because these foods are plentiful in the diets offered by their parents, who also tend to be overweight (Kit, Ogden, & Flegal, 2014). Frequent eating out—which increases parents' and children's consumption of high-calorie fast foods—is linked to overweight. And eating out likely plays a major role in the relationship between mothers' employment hours and elevated BMI among school-age children (Morrissey, Dunifon, & Kalil, 2011). Demanding work schedules reduce the time parents have for healthy meal preparation.

Furthermore, some parents anxiously overfeed, interpreting almost all their child's discomforts as a desire for food—a practice

ZACK WITTMAN FOR THE BOSTON GLOBE VIA GETTY IMAGES

This 9-year-old, living in shelter housing with her mother, is at high risk for obesity. Home-life stressors, including poverty, single parenthood, noise, crowding, and clutter, contribute to overeating by impairing children's self-regulation.

common among immigrant parents and grandparents who, as children themselves, may have survived periods of food deprivation. Still other parents are overly controlling, restricting when, what, and how much their child eats and worrying about weight gain (Couch et al., 2014; Jansen et al., 2012). In each case, parents undermine children's ability to regulate their own food intake.

Because of these experiences, obese children soon develop maladaptive eating habits. They are more responsive than normal-weight individuals to external stimuli associated with food—taste, sight, smell, time of day, and food-related words—and less responsive to internal hunger cues (Temple et al., 2007). Furthermore, a stressful family life contributes to children's diminished self-regulatory capacity, amplifying uncontrolled eating (see the Social Issues: Health box above).

Another factor implicated in weight gain is insufficient sleep (Hakim, Kheirandish-Gozal, & Gozal, 2015). Reduced sleep may increase time available for eating while leaving children too fatigued for physical activity. It also disrupts the brain's regulation of hunger and metabolism.

The rise in childhood obesity is due in part to the many hours U.S. children devote to screen media. In a study that tracked children's TV viewing from ages 4 to 11, the more TV children watched, the more body fat they added: By age 11, children who devoted more than 3 hours per day to TV accumulated 40 percent more fat than those devoting less than 1¾ hours (Proctor et al., 2003). TV and Internet ads encourage children to eat unhealthy snacks: The more ads they watch, the greater their consumption of high-calorie snack foods. Children permitted to have a TV in their bedroom—a practice linked to especially high TV viewing—are at even further risk for overweight (Borghese et al., 2015; Soos et al., 2014). And heavy viewing likely subtracts from time spent in physical exercise.

**Consequences of Obesity.** Obese children are at risk for lifelong health problems. Symptoms that begin to appear in the early school years—high blood pressure, high cholesterol levels, respiratory abnormalities, insulin resistance, and inflammatory reactions—are powerful predictors of heart disease, circulatory difficulties, type 2 diabetes, gallbladder disease, sleep and digestive disorders, many forms of cancer, and premature death. Furthermore, obesity has caused a dramatic rise in cases of diabetes in children, sometimes leading to early, severe complications, including stroke, kidney failure, and circulatory problems that heighten the risk of eventual blindness and leg amputation (Biro & Wien, 2010; Yanovski, 2015).

Unfortunately, physical attractiveness is a powerful predictor of social acceptance. In Western societies, both children and adults stereotype obese youngsters as lazy, sloppy, ugly, stupid, self-doubting, and deceitful (Penny & Haddock, 2007; Tiggemann & Anesbury, 2000). In school, obese children and adolescents are often socially isolated. They report more emotional, social, and school difficulties, including peer teasing, rejection, and consequent low self-esteem (van Grieken et al., 2013; Zeller & Modi, 2006). They also tend to achieve less well than their healthy-weight agemates (Datar & Sturm, 2006).

Persistent obesity from childhood into adolescence predicts serious psychological disorders, including severe anxiety and depression, defiance and aggression, and suicidal thoughts and behavior (Lopresti & Drummond, 2013; Puhl & Latner, 2007). As we will see in Chapter 13, these consequences combine with continuing discrimination to further impair physical health and to reduce life chances in close relationships and employment.

**Treating Obesity.** In Mona's case, the school nurse suggested that Mona and her obese mother enter a weight-loss program together. But Mona's mother, unhappily married for many years, had her own reasons for overeating and rejected this idea. In one study, nearly 70 percent of parents judged their overweight or obese children to have a normal weight (Jones et al., 2011). Consistent with these findings, most obese children do not get any treatment.

The most effective interventions are family-based and focus on changing weight-related behaviors (Seburg et al., 2015). In

one program, both parent and child revised eating patterns, exercised daily, and reinforced each other with praise and points for progress, which they exchanged for special activities and times together. The more weight parents lost, the more their children lost. Follow-ups after 5 and 10 years showed that children maintained their weight loss more effectively than adults—a finding that underscores the importance of early intervention (Epstein, Roemmich, & Raynor, 2001; Wrotniak et al., 2004). Monitoring dietary intake and physical activity is important. Small wireless sensors that sync with mobile devices, enabling individualized goal-setting and tracking of progress through game-like features, are effective (Calvert, 2015; Seburg et al., 2015). But these interventions work best when parents' and children's weight problems are not severe.

Children consume one-third of their daily caloric intake at school. Therefore, schools can help reduce obesity by serving healthier meals and ensuring regular physical activity (Lakshman, Elks, & Ong, 2012). Because obesity is expected to rise further without broad prevention strategies, many U.S. states and cities have passed obesity-reduction legislation. Among measures taken are weight-related school screenings for all children, improved school nutrition standards that include food and beverages sold outside of meals, additional school recess time and physical education, and obesity awareness and weight-reduction programs as part of school curricula. A review of these

ARIEL SKELLEY/BLEND IMAGES/GETTY IMAGES

A mother and son reinforce each other's efforts to lose weight and get in shape. The most effective interventions for childhood obesity focus on changing the whole family's behaviors, emphasizing fitness and healthy eating.

school-based efforts reported impressive benefits (Waters et al., 2011). Obesity prevention in schools was more successful in reducing 6- to 12-year-olds' BMIs than programs delivered in other community settings, perhaps because schools are better able to provide long-term, comprehensive intervention.

### LOOK and LISTEN

Contact your state and city governments to find out about their childhood obesity-prevention legislation. Can policies be improved?

## Vision and Hearing

The most common vision problem in middle childhood is *myopia*, or nearsightedness. By the end of the school years, it affects nearly 25 percent of children—a rate that rises to 60 percent by early adulthood (Rahi, Cumberland, & Peckham, 2011).

Heritability estimates based on comparisons of twins and other family members reveal a moderate genetic influence (Guggenheim et al., 2015). And worldwide, myopia occurs far more frequently in Asian than in white populations (Morgan, Ohno-Matsui, & Saw, 2012). Early biological trauma also can induce myopia. School-age children with low birth weights show an especially high rate, believed to result from immaturity of visual structures, slower eye growth, and a greater incidence of eye disease (Molloy et al., 2013).

When parents warn their children not to read in dim light or sit too close to the TV or computer screen, their concern (“You’ll ruin your eyes!”) is well-founded. In diverse cultures, the more time children spend reading, writing, using the computer, and doing other close work, the more likely they are to be myopic. In school-age children who spend more time playing outdoors, the incidence of myopia is reduced (Russo et al., 2014). Myopia is one of the few health conditions to increase with SES. Fortunately, it can be overcome easily with corrective lenses.

During middle childhood, the Eustachian tube (canal that runs from the inner ear to the throat) becomes longer, narrower, and more slanted, preventing fluid and bacteria from traveling so easily from the mouth to the ear. As a result, middle-ear infections, common in infancy and early childhood, become less frequent. Still, about 3 to 4 percent of the school-age population, and as many as 20 percent of low-SES children, develop persistent hearing loss as a result of repeated untreated infections (Aarhus et al., 2015; Ryding et al., 2002). With regular screening for both vision and hearing, defects can be corrected before they lead to serious learning difficulties.

## Illnesses

Children experience a somewhat higher rate of illness during the first two years of elementary school than later because of exposure to sick children and an immune system that is still

developing. About 20 to 25 percent of U.S. children have chronic diseases and conditions (including physical disabilities) (Compas et al., 2012). By far the most common—accounting for about one-third of childhood chronic illness and the most frequent cause of school absence and childhood hospitalization—is *asthma*, in which the bronchial tubes (passages that connect the throat and lungs) are highly sensitive (Basinger, 2013). In response to a variety of stimuli, such as cold weather, infection, exercise, allergies, and emotional stress, they fill with mucus and contract, leading to coughing, wheezing, and serious breathing difficulties.

The prevalence of asthma in the United States has increased steadily over the past several decades, with nearly 8 percent of children affected. Although heredity contributes to asthma, researchers believe that environmental factors are necessary to spark the illness. Boys, African-American children, and children who were born underweight, whose parents smoke, and who live in poverty are at greatest risk (Centers for Disease Control and Prevention, 2015a). The higher rate and greater severity of asthma among African-American and poverty-stricken children may be the result of pollution in inner-city areas (which triggers allergic reactions), stressful home lives, and lack of access to good health care. Childhood obesity is also related to asthma (Hampton, 2014). High levels of blood-circulating inflammatory substances associated with body fat and the pressure of excess weight on the chest wall may be responsible.

About 2 percent of U.S. children have more severe chronic illnesses, such as sickle cell anemia, cystic fibrosis, diabetes, arthritis, cancer, and AIDS. Painful medical treatments, physical discomfort, and changes in appearance often disrupt the sick child’s daily life, making it difficult to concentrate in school and separating the child from peers. As the illness worsens, family and child stress increases (Marin et al., 2009; Rodriguez, Dunn, & Compas, 2012). For these reasons, chronically ill children are at risk for academic, emotional, and social difficulties.

A strong link exists between good family functioning and child well-being for chronically ill children, just as it does for physically healthy children (Compas et al., 2012). Interventions that foster positive family relationships help parent and child cope with the disease and improve adjustment. These include health education, counseling, parent and peer support groups, and disease-specific summer camps, which teach children self-help skills and give parents time off from the demands of caring for an ill youngster.

## Unintentional Injuries

As we conclude our discussion of threats to school-age children’s health, let’s return to the topic of unintentional injuries (discussed in detail in Chapter 7). As Figure 9.2 shows, injury fatalities increase from middle childhood into adolescence, with rates for boys rising considerably above those for girls.

Motor vehicle accidents, involving children as passengers or pedestrians, continue to be the leading cause of injury, followed

**FIGURE 9.2 U.S. rates of injury mortality from middle childhood to adolescence.** Injury fatalities increase with age, and the gap between boys and girls expands. Motor vehicle (passenger and pedestrian) accidents are the leading cause, with bicycle injuries next in line. (Based on Centers for Disease Control and Prevention, 2015p.)

by bicycle accidents (Bailar-Heath & Valley-Gray, 2010). Pedestrian injuries most often result from midblock dart-outs, bicycle accidents from disobeying traffic signals and rules. When many stimuli impinge on young school-age children at once, they often fail to think before they act. They need frequent reminders, supervision, and prohibitions against venturing into busy traffic on their own.

Effective school- and community-based prevention programs use extensive modeling and rehearsal of safety practices, give children feedback about their performance along with praise and tangible rewards for acquiring safety skills, and provide occasional booster sessions. Targeting specific injury risks (such as traffic safety) rather than many risks at once yields longer-lasting results (Nauta et al., 2014). As part of these programs, parents, who often overestimate their child's safety knowledge and physical abilities, must be educated about children's age-related safety capacities.

One vital safety measure is legally requiring that children wear protective helmets while bicycling, in-line skating, skateboarding, or using scooters. This precaution leads to a 9 percent reduction in head injuries, a leading cause of permanent disability and death in school-age children (Karkhaneh et al., 2013). Combining helmet use with other community-based prevention strategies is especially effective.

Highly active, impulsive, risk-taking children, many of whom are boys, remain particularly susceptible to injury in middle childhood. Parents tend to be lax in intervening in the dangerous behaviors of such children, especially under conditions of marital conflict or other forms of stress (Schwebel et al., 2011, 2012). The greatest challenge for injury-control programs is reaching these youngsters and reducing their exposure to hazardous situations.

## Motor Development and Play

**9.6** Cite major changes in motor development and play during middle childhood.

Visit a park on a pleasant weekend afternoon, and watch several preschool and school-age children at play. You will see that gains in body size and muscle strength support improved motor coordination in middle childhood. And greater cognitive and social maturity enables older children to use their new motor skills in more complex ways. A major change in children's play takes place at this time.

### Gross-Motor Development

During the school years, running, jumping, hopping, and ball skills become more refined. Third to sixth graders burst into sprints as they race across the playground, jump quickly over rotating ropes, engage in intricate hopscotch patterns, kick and dribble soccer balls, bat at balls pitched by their classmates, and balance adeptly as they walk heel-to-toe across narrow ledges. These diverse skills reflect gains in four basic motor capacities:

- *Flexibility.* Compared with preschoolers, school-age children are physically more pliable and elastic, a difference evident as they swing bats, kick balls, jump over hurdles, and execute tumbling routines.

© ZUMA PRESS, INC./ALAMY

Improved physical flexibility, balance, agility, and force, along with more efficient information processing, promote gains in school-age children's gross-motor skills.

- *Balance.* Improved balance supports many athletic skills, including running, hopping, skipping, throwing, kicking, and the rapid changes of direction required in many team sports.
- *Agility.* Quicker and more accurate movements are evident in the fancy footwork of dance and cheerleading and in the forward, backward, and sideways motions used to dodge opponents in tag and soccer.
- *Force.* Older youngsters can throw and kick a ball harder and propel themselves farther off the ground when running and jumping than they could at earlier ages (Haywood & Getchell, 2014).

Along with body growth, more efficient information processing plays a vital role in improved motor performance. During middle childhood, the capacity to react only to relevant information increases. And steady gains in reaction time occur, including anticipatory responding to visual stimuli, such as a thrown ball or a turning jump rope. Ten-year-olds react twice as quickly as 5-year-olds (Debrabant et al., 2012; Kail, 2003). Because 5- to 7-year-olds are seldom successful at batting a thrown ball, T-ball is more appropriate for them than baseball. Similarly, handball, four-square, and kickball should precede instruction in tennis, basketball, and football.

Children's gross-motor activity not only benefits from but contributes to cognitive development. Physical fitness predicts improved executive function, memory, and academic achievement in middle childhood (Chaddock et al., 2011). Exercise-induced changes in the brain seem to be responsible: Brain-imaging research reveals that structures supporting attentional control and memory are larger, and myelination of neural fibers within them greater, in better-fit than in poorly-fit children (Chaddock et al., 2010a, 2010b; Chaddock-Heyman et al., 2014). Furthermore, children who are physically fit—and those assigned to a yearlong, one-hour-per-day school fitness program—activate these brain structures more effectively while performing executive function tasks (Chaddock et al., 2012; Chaddock-Heyman et al., 2013). Mounting evidence supports the role of vigorous exercise in optimal brain and cognitive functioning in childhood—a relationship that persists throughout the lifespan.

## Fine-Motor Development

Fine-motor development also improves over the school years. On rainy afternoons, Joey and Lizzie experimented with yo-yos, built model airplanes, and wove potholders on small looms. Like many children, they took up musical instruments, which demand considerable fine-motor control.

Gains in fine-motor skill are especially evident in children's writing and drawing. By age 6, most children can print the alphabet, their first and last names, and the numbers from 1 to 10 with reasonable clarity. Their writing is large, however, because they make strokes using the entire arm rather than just the wrist and fingers. Children usually master uppercase letters first because

their horizontal and vertical motions are easier to control than the small curves of the lowercase alphabet. Legibility of writing gradually increases as children produce more accurate letters with uniform height and spacing.

Children's drawings show dramatic gains in middle childhood. By the end of the preschool years, children can accurately copy many two-dimensional shapes, and they integrate these into their drawings. Some depth cues have also begun to appear, such as making distant objects smaller than near ones (Braine et al., 1993). Around 9 to 10 years, the third dimension is clearly evident through overlapping objects, diagonal placement, and converging lines. Furthermore, as Figure 9.3 shows, school-age children not only depict objects in considerable detail but also better relate them to one another as part of an organized whole (Case & Okamoto, 1996).

CHILDREN'S MUSEUM OF THE ARTS, NEW YORK, PERMANENT COLLECTION

**FIGURE 9.3** Increase in organization, detail, and depth cues in school-age children's drawings. Compare both drawings to the one by a 5-year-old in Figure 7.4 on page 224. In the drawing by an 8-year-old on the top, notice how all parts are depicted in relation to one another and with greater detail. Integration of depth cues increases dramatically over the school years, as shown in the drawing on the bottom, by an 11-year-old. Here, depth is indicated by overlapping objects, diagonal placement, and converging lines, as well as by making distant objects smaller than near ones.

## Sex Differences

Sex differences in motor skills extend into middle childhood and, in some instances, become more pronounced. Girls have an edge in fine-motor skills of handwriting and drawing and in gross-motor capacities that depend on balance and agility, such as hopping and skipping (Haywood & Getchell, 2014). But boys outperform girls on all other gross-motor skills, especially throwing and kicking.

School-age boys' genetic advantage in muscle mass is not large enough to account for their gross-motor superiority. Rather, the social environment plays a larger role. Parents hold higher expectations for boys' athletic performance, and children readily absorb these messages. From first through twelfth grades, girls are less positive than boys about the value of sports and their own sports ability—differences explained in part by parental beliefs (Anderson, Hughes, & Fuemmeler, 2009; Fredricks & Eccles, 2002). The more strongly girls believe that females are incompetent at sports (such as hockey or soccer), the lower they judge their own ability and the poorer they actually perform (Belcher et al., 2003; Chalabaev, Sarrazin, & Fontayne, 2009).

Educating parents about the minimal differences between school-age boys' and girls' physical capacities and sensitizing them to unfair biases against promotion of girls' athletic ability may help increase girls' self-confidence and participation in athletics. Greater emphasis on skill training for girls, along with increased attention to their athletic achievements, is also likely to help. As a positive sign, compared with a generation ago, many more girls now participate in individual and team sports, though their involvement continues to lag behind boys' (Kanters et al., 2013; Sabo & Veliz, 2011). Middle childhood is a crucial time to encourage girls' sports participation because during this period, children start to discover what they are good at and make some definite skill commitments.

## Games with Rules

The physical activities of school-age children reflect an important advance in quality of play: Games with rules become common. Children around the world engage in an enormous variety of informally organized games, including variants on popular sports such as soccer, baseball, and basketball. In addition to the best-known childhood games, such as tag, jacks, and hopscotch, children have invented hundreds of other games, including red rover, statues, leapfrog, kick the can, and prisoner's base.

Gains in perspective taking—in particular, the ability to understand the roles of several players in a game—permit this transition to rule-oriented games. These play experiences, in turn, contribute greatly to emotional and social development. Child-invented games usually rely on simple physical skills and a sizable element of luck. As a result, they rarely become contests of individual ability. Instead, they permit children to try out different styles of cooperating, competing, winning, and losing with

© ELIZABETH CREWS/THE IMAGE WORKS

A group of boys gather in their schoolyard for a pick-up basketball game. Unlike their economically advantaged agetmates, children in low-SES communities often play child-organized games, which serve as rich contexts for social learning.

little personal risk. Also, in their efforts to organize a game, children discover why rules are necessary and which ones work well.

Compared with past generations, school-age children today spend less time engaged in informal outdoor play—a change that reflects parental concern about neighborhood safety as well as competition for children's time from TV and other screen media. Another factor is the rise in adult-organized sports, such as Little League baseball and soccer and hockey leagues, which fill many hours that children from economically advantaged families used to devote to spontaneous play.

In village societies and developing countries and in many low-SES communities in industrialized nations, children's informal sports and games remain common. In an ethnographic study in two communities—a refugee camp in Angola, Africa, and a Chicago public housing complex—the overwhelming majority of 6- to 12-year-olds engaged in child-organized games at least once a week, and half or more did so nearly every day. Play in each context reflected cultural values (Guest, 2013). In the Angolan community, games emphasized imitation of social roles, such as soccer moves of admired professional players. Games in Chicago, in contrast, were competitive and individualistic. In ballgames, for example, children often made sure peers noticed when they batted or fielded balls particularly well.

## Adult-Organized Youth Sports

Nearly half of U.S. children—60 percent of boys and 47 percent of girls—participate in organized sports outside of school hours at some time between ages 5 and 18 (SFIA, 2015). Children in low-SES communities, however, are profoundly underserved, with girls and ethnic minorities having especially limited opportunities. In a comparison of two neighborhoods in Oakland,

## Applying what we Know

### Providing Developmentally Appropriate Organized Sports in Middle Childhood

SUGGESTION	DESCRIPTION
Build on children's interests.	Permit children to select from among appropriate activities the ones that suit them best. Do not push children into sports they do not enjoy.
Teach age-appropriate skills.	For children younger than age 9, emphasize basic skills, such as kicking, throwing, and batting, and simplified games that grant all participants adequate playing time.
Emphasize enjoyment.	Permit children to progress at their own pace and to play for the fun of it, whether or not they become expert athletes.
Limit the frequency and length of practices.	Adjust practice time to children's attention spans and need for unstructured time with peers, with family, and for homework. Two practices a week, each no longer than 30 minutes for younger school-age children and 60 minutes for older school-age children, are sufficient.
Focus on personal and team improvement.	Emphasize effort, skill gains, and teamwork rather than winning. Avoid criticism for errors and defeat, which promotes anxiety and avoidance of athletics.
Discourage unhealthy competition.	Avoid all-star games and championship ceremonies that recognize individuals. Instead, acknowledge all participants.
Permit children to contribute to rules and strategies.	Involve children in decisions aimed at ensuring fair play and teamwork. To strengthen desirable responses, reinforce compliance rather than punishing noncompliance.

California, 67 percent of teenage girls in a well-to-do area were members of athletic teams (Team Up for Youth, 2014). Just a few miles away, in a poverty-stricken, largely minority part of the city, a mere 11 percent were involved in organized sports.

For most children, joining community athletic teams is associated with increased self-esteem and social skills (Daniels & Leaper, 2006). Children who view themselves as good at sports are more likely to continue playing on teams in adolescence, which predicts greater participation in sports and other physical fitness activities in early adulthood (Kjønniksen, Anderssen, & Wold, 2009).

In some cases, though, the arguments of critics—that youth sports overemphasize competition and substitute adult control for children's natural experimentation with rules and strategies—are valid. Coaches and parents who criticize rather than encourage can prompt intense anxiety in some children, setting the stage for emotional difficulties and early athletic dropout, not elite performance (Wall & Côté, 2007). See Applying What We Know above for ways to ensure that athletic leagues provide children with positive learning experiences.

### LOOK and LISTEN

Observe a youth athletic-league game, such as soccer, baseball, or hockey. Do coaches and parents encourage children's effort and skill gains, or are they overly focused on winning? Cite examples of adult and child behaviors.

## Shadows of Our Evolutionary Past

While watching children in your neighborhood park, notice how they sometimes wrestle, roll, hit, and run after one another, alternating roles while smiling and laughing. This friendly chasing and play-fighting is called **rough-and-tumble play**. It emerges in the preschool years and peaks in middle childhood (Pellegrini, 2006). Children in many cultures engage in it with peers whom they like especially well.

Children's rough-and-tumble play resembles the social behavior of many other young mammals. It seems to originate in parents' physical play with babies, especially fathers' with sons (see pages 203–204 in Chapter 6). And it is more common among boys, probably because prenatal exposure to androgens predisposes boys toward active play (see Chapter 8).

In our evolutionary past, rough-and-tumble play may have been important for developing fighting skill. It also helps children form a **dominance hierarchy**—a stable ordering of group members that predicts who will win when conflict arises. Observations of arguments, threats, and physical attacks between children reveal a consistent lineup of winners and losers that becomes increasingly stable in middle childhood, especially among boys. Once school-age children establish a dominance hierarchy, hostility is rare. Children seem to use play-fighting as a safe context to assess the strength of a peer before challenging that peer's dominance (Fry, 2014; Roseth et al., 2007). Rough-and-tumble play offers lessons in how to handle combative interactions with restraint.

© CLEVE BRYANT/PHOTOEDIT

In our evolutionary past, rough-and-tumble play—which can be distinguished from aggression by its friendly quality—may have been important for developing fighting skill and establishing dominance hierarchies.

As children reach puberty, individual differences in strength become apparent, and rough-and-tumble play declines. When it does occur, its meaning changes: Adolescent boys' rough-and-tumble is linked to aggression (Pellegrini, 2003). Unlike children, teenage rough-and-tumble players “cheat,” hurting their opponent. In explanation, boys often say that they are retaliating, apparently to reestablish dominance. Thus, a play behavior that limits aggression in childhood becomes a context for hostility in adolescence.

## Physical Education

Physical activity supports many aspects of children's development—physical health, self-esteem, and cognitive and social skills. Yet to devote more time to academic instruction, 80 percent of U.S. school districts no longer require a daily recess in the elementary school grades (Centers for Disease Control and Prevention, 2014b). Although most U.S. states require some physical education, only six do so in every grade, and only one mandates at least 30 minutes per school day in elementary school and 45 minutes in middle and high school. Not surprisingly, physical inactivity among school-age children is pervasive: Fewer than 30 percent of 6- to 17-year-olds engage in at least moderate-intensity activity for 60 minutes per day, including

some vigorous activity (involving breathing hard and sweating) on three of those days—the U.S. government recommendations for good health (Centers for Disease Control and Prevention, 2014f). With the transition to adolescence, physical activity declines, more for girls than for boys.

Many experts believe that schools should not only offer more frequent physical education classes but also reduce the emphasis placed on competitive sports, which are unlikely to reach the least physically fit youngsters. Instead, programs should emphasize informal games and individual exercise—pursuits most likely to endure. Physically active children tend to become active adults who reap many benefits (Kjønniksen, Torsheim, & Wold, 2008). These include greater physical strength, resistance to many illnesses (from colds and flu to cancer, diabetes, and heart disease), enhanced psychological well-being, and a longer life.

## Ask yourself

**CONNECT** Select one of the following health problems of middle childhood: obesity, myopia, asthma, or unintentional injuries. Explain how both genetic and environmental factors contribute to it.

**APPLY** Nine-year-old Allison thinks she isn't good at sports, and she doesn't like physical education class. Suggest strategies her teacher can use to improve her pleasure and involvement in physical activity.

**REFLECT** Did you participate in adult-organized sports as a child? If so, what kind of climate for learning did coaches and parents create?

## COGNITIVE DEVELOPMENT

“Finally!” 6-year-old Lizzie exclaimed the day Rena enrolled her in elementary school. “Now I get to go to real school, just like Joey!” Lizzie confidently walked into a combined kindergarten–first-grade class in her neighborhood school, ready for a more disciplined approach to learning. In a single morning, she and her classmates met in reading groups, wrote in journals, worked on addition and subtraction, and sorted leaves gathered for a science project. As Lizzie and Joey moved through the elementary school grades, they tackled increasingly complex projects and became more accomplished at reading, writing, math skills, and general knowledge of the world.

To understand the cognitive attainments of middle childhood, we turn to research inspired by Piaget's theory and the information-processing perspective. Then we look at expanding definitions of intelligence that help us appreciate individual differences. Our discussion continues with language, which blossoms further in these years. Finally, we consider the role of schools in children's development.

## Piaget's Theory: The Concrete Operational Stage

**9.7** What are the major characteristics of concrete operational thought?

**9.8** Discuss follow-up research on concrete operational thought.

When Lizzie visited my child development class at age 4, Piaget's conservation problems confused her (see Chapter 7, page 229). For example, when water was poured from a tall, narrow container into a short, wide one, she insisted that the amount of water had changed. But when Lizzie returned at age 8, she found this task easy. "Of course it's the same!" she exclaimed. "The water's shorter, but it's also wider. Pour it back," she instructed the college student who was interviewing her. "You'll see, it's the same amount!"

### Concrete Operational Thought

Lizzie has entered Piaget's **concrete operational stage**, which extends from about 7 to 11 years. Compared with early childhood, thought is more logical, flexible, and organized.

**Conservation.** The ability to pass *conservation tasks* provides clear evidence of *operations*—mental actions that obey logical rules. Notice how Lizzie is capable of *decentration*, focusing on several aspects of a problem and relating them, rather than centering on just one. She also demonstrates **reversibility**, the capacity to think through a series of steps and then mentally reverse direction, returning to the starting point. Recall from Chapter 7 that reversibility is part of every logical operation. It is solidly achieved in middle childhood.

**Classification.** Between ages 7 and 10, children pass Piaget's *class inclusion problem* (see page 230). This indicates that they are more aware of classification hierarchies and can focus on relations between a general category and two specific categories at the same time—on three relations at once. They are better able to inhibit their habitual strategy of perceptually comparing the two specific categories (blue flowers and yellow flowers) in favor of relating each specific category to its less-obvious general category (Borst et al., 2013). School-age children's enhanced classification skills are evident in their enthusiasm for collecting treasured objects. At age 10, Joey spent hours sorting and resorting his baseball cards, grouping them first by league and team, then by playing position and batting average. He could separate the players into a variety of classes and subclasses and easily rearrange them.

**Seriation.** The ability to order items along a quantitative dimension, such as length or weight, is called **seriation**. To test for it, Piaget asked children to arrange sticks of different lengths from shortest to longest. Older preschoolers can put the sticks

© LAURA DWIGHT PHOTOGRAPHY

An improved ability to categorize underlies children's interest in collecting objects during middle childhood. This 10-year-old sorts and organizes his extensive rock and mineral collection.

in a row, but they do so haphazardly, making many errors. In contrast, 6- to 7-year-olds create the series efficiently, moving in an orderly sequence from the smallest stick, to the next largest, and so on.

The concrete operational child can also seriate mentally, an ability called **transitive inference**. In a well-known transitive inference problem, Piaget showed children pairings of sticks of different colors. From observing that Stick *A* is longer than Stick *B* and Stick *B* is longer than Stick *C*, children must infer that *A* is longer than *C*. Like Piaget's class inclusion task, transitive inference requires children to integrate three relations at once—in this instance, *A–B*, *B–C*, and *A–C*. As long as they receive help in remembering the premises (*A–B* and *B–C*), 7- to 8-year-olds can grasp transitive inference (Wright, 2006). And when the task is made relevant to children's everyday experiences—for example, based on winners of races between pairs of cartoon characters—6-year-olds perform well (Wright, Robertson, & Hadfield, 2011).

**Spatial Reasoning.** Piaget found that school-age children's understanding of space is more accurate than that of preschoolers. To illustrate, let's consider children's **cognitive maps**—their mental representations of spaces such as a classroom, school, or neighborhood. Drawing or reading a map of a large-scale space (school or neighborhood) requires considerable perspective-

taking skill. Because the entire space cannot be seen at once, children must infer its overall layout by relating its separate parts.

Preschoolers and young school-age children include *landmarks* on the maps they draw of a single room, but their arrangement is not always accurate. They do better when asked to place stickers showing the location of furniture and people on a map of the room. But if the map is rotated to a position other than the room's orientation, they have difficulty (Liben & Downs, 1993). In identifying landmarks on a rotated map, 7-year-olds are aided by the opportunity to walk through the room (Lehning et al., 2003). Actively exploring it permits them to experience landmarks from different vantage points, which fosters a more flexible mental representation.

With respect to large-scale outdoor environments, not until age 9 can many children accurately place stickers on a map to indicate landmarks. Children who spontaneously use strategies that help them align the map with their current location in the space—rotating the map or tracing their route on it—show better performance (Liben et al., 2013). Around this age, the maps children draw of large-scale spaces become better organized, showing landmarks along an *organized route of travel*. At the same time, children are able to give clear, well-organized instructions for getting from one place to another.

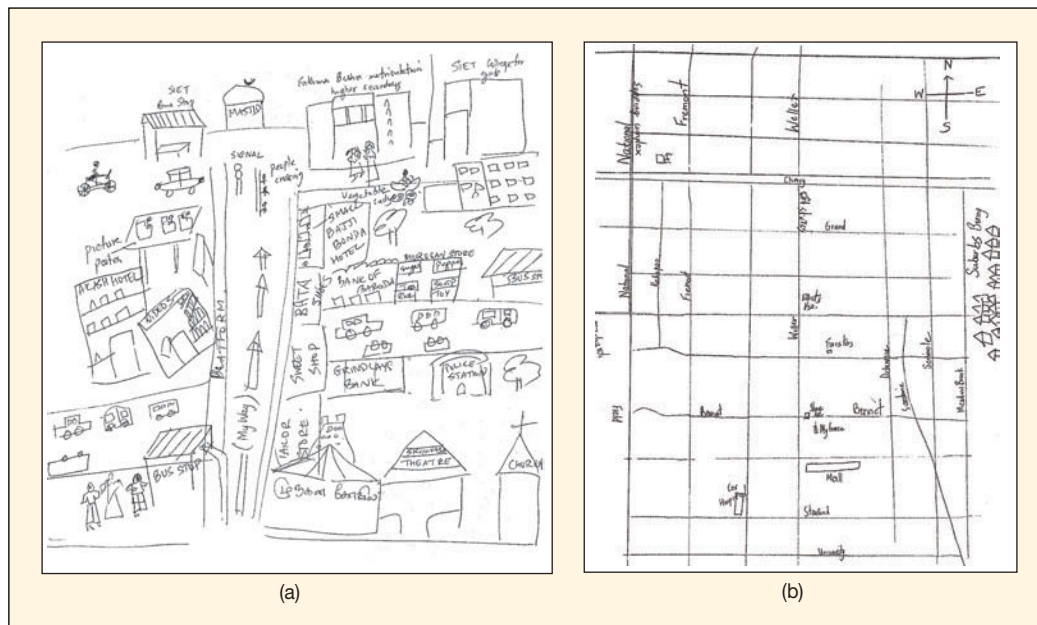

At the end of middle childhood, most children can form an accurate *overall view of a large-scale space*. And they readily draw and read maps, even when the orientation of the map and the space it represents do not match (Liben, 2009). Ten- to 12-year-olds also grasp the notion of *scale*—the proportional

relation between a space and its representation on a map (Liben, 2006). And they appreciate that in interpreting map symbols, a mapmaker's assigned meaning supersedes physical resemblance—for example, that green dots (not red dots) may indicate where fire trucks are located (Myers & Liben, 2008).

### LOOK and LISTEN

Ask a 6- to 8-year-old and a 9- to 12-year-old to draw a neighborhood map showing important landmarks, such as the school, a friend's house, or a shopping area. In what ways do the children's maps differ?

Cultural frameworks influence children's map making. In many non-Western communities, people rarely use maps for way-finding but rely on information from neighbors, street vendors, and shopkeepers. Also, compared to their Western age-mates, non-Western children less often ride in cars and more often walk, which results in intimate neighborhood knowledge. When a researcher had 12-year-olds in small cities in India and in the United States draw maps of their neighborhoods, the Indian children represented a rich array of landmarks and aspects of social life, such as people and vehicles, in a small area surrounding their home. The U.S. children, in contrast, drew a more formal, extended space, highlighting main streets and key directions (north–south, east–west) but including few landmarks (see Figure 9.4) (Parameswaran, 2003). Although the U.S. children's

**FIGURE 9.4** Maps drawn by older school-age children from India and the United States. (a) The Indian child depicted many landmarks and features of social life in a small area near her home. (b) The U.S. child drew a more extended space and highlighted main streets and key directions but included few landmarks and people. (From G. Parameswaran, 2003, "Experimenter Instructions as a Mediator in the Effects of Culture on Mapping One's Neighborhood," *Journal of Environmental Psychology*, 23, pp. 415–416. Copyright © 2003, reprinted with permission from Elsevier, Ltd., conveyed through Copyright Clearance Center, Inc.)

maps scored higher in cognitive maturity, this difference reflected cultural interpretations of the task. When asked to create a map to “help people find their way,” the Indian children drew spaces as far-reaching and organized as the U.S. children’s.

## Limitations of Concrete Operational Thought

As the name of this stage suggests, concrete operational thinking suffers from one important limitation: Children think in an organized, logical fashion only when dealing with concrete information they can perceive directly. Their mental operations work poorly with abstract ideas—ones not apparent in the real world. Consider children’s solutions to transitive inference problems. When shown pairs of sticks of unequal length, Lizzie easily engaged in transitive inference. But she had difficulty with a hypothetical version of this task: “Susan is taller than Sally, and Sally is taller than Mary. Who is the tallest?” Not until age 11 or 12 can children typically solve this problem.

That logical thought is at first tied to immediate situations helps account for a special feature of concrete operational reasoning: Children master concrete operational tasks step by step. For example, they usually grasp conservation of number first, followed by length, liquid, and mass, and then weight. This *continuum of acquisition* (or gradual mastery) of logical concepts is another indication of the limitations of concrete operational thinking (Fischer & Bidell, 1991). Rather than coming up with general logical principles that they apply to all relevant situations, school-age children seem to work out the logic of each problem separately.

## Follow-Up Research on Concrete Operational Thought

According to Piaget, brain development combined with experience in a rich and varied external world should lead children everywhere to reach the concrete operational stage at about the same time. Yet much evidence indicates that specific cultural and school practices have much to do with mastery of Piagetian tasks (Rogoff, 2003). And information-processing research helps explain the gradual mastery of logical concepts in middle childhood.

**The Impact of Culture and Schooling.** In village societies, conservation is often delayed. Among the Hausa of Nigeria, who live in small agricultural settlements and rarely send their children to school, even basic conservation tasks—number, length, and liquid—are not understood until age 11 or later (Fahrmeier, 1978). This suggests that participating in relevant everyday activities helps children master conservation and other Piagetian problems. Joey and Lizzie, for example, think of fairness in terms of equal distribution—a value emphasized in their culture. They frequently divide materials, such as Halloween

© LAUREN GREENFIELD/INSTITUTE

A Zinacanteco Indian girl of southern Mexico learns the centuries-old practice of backstrap weaving. Although Zinacanteco children might do poorly on Piaget’s tasks, they are adept at the complex mental transformations involved in converting warp strung on a loom into woven cloth.

treats or lemonade, equally among their friends. Because they often see the same quantity arranged in different ways, they grasp conservation early.

The experience of going to school promotes mastery of Piagetian tasks. When children of the same age are tested, those who have been in school longer do better on transitive inference problems (Artman & Cahan, 1993). Opportunities to seriate objects, to learn about order relations, and to remember the parts of complex problems are probably responsible. Yet certain informal nonschool experiences can also foster operational thought. Around age 7 to 8, Zinacanteco Indian girls of southern Mexico, who learn to weave elaborately designed fabrics as an alternative to schooling, engage in mental transformations to figure out how a warp strung on a loom will turn out as woven cloth—reasoning expected at the concrete operational stage (Maynard & Greenfield, 2003). North American children of the same age, who do much better than Zinacanteco children on Piagetian tasks, have great difficulty with these weaving problems.

On the basis of such findings, some investigators have concluded that the forms of logic required by Piagetian tasks are heavily influenced by training, context, and cultural conditions. Does this view remind you of Vygotsky’s sociocultural theory, discussed in earlier chapters?

**An Information-Processing View of Concrete Operational Thought.** The gradual mastery of logical concepts in middle childhood raises a familiar question about Piaget’s theory: Is an abrupt stagewise transition to logical thought the best way to describe cognitive development in middle childhood?

Some *neo-Piagetian theorists* argue that the development of operational thinking can best be understood in terms of expansion of information-processing capacity rather than a sudden shift to a new stage. For example, Robbie Case (1996, 1998) proposed that change within each Piagetian stage and movement between stages are largely due to gains in the efficiency with which children use their limited working memories. According to Case, with brain development and practice, cognitive schemes are applied more rapidly, gradually demanding less attention and becoming automatic. This frees up space in working memory so children can focus on combining old schemes and generating new ones. For instance, as children's understanding that the height of a liquid changes after it is poured into a differently shaped container becomes routine, they notice that the width of the water changes as well. Soon they coordinate these observations, and they grasp conservation of liquid. Then, as this logical idea becomes well-practiced, children transfer it to more demanding situations, such as weight.

Once the schemes of a Piagetian stage are sufficiently automatic, enough working memory is available to integrate them into an improved, broadly applicable representation. As a result, children transition from concrete operations to the complex, systematic reasoning of formal operational thought, which enables them to think effectively in a wider range of situations. We will discuss the formal operational stage in Chapter 11.

Case's theory, along with similar neo-Piagetian perspectives, helps explain why children's understandings appear in specific situations at different times rather than being mastered all at once (Andrews & Halford, 2011; Barrouillet & Gaillard, 2011a). First, different forms of the same logical insight, such as the various conservation tasks, vary in their processing demands, with those acquired later requiring more space in working memory. Second, as we have seen, children's experiences with different types of tasks vary widely, affecting their performance. Compared with Piaget's theory, neo-Piagetian approaches better account for unevenness in cognitive development.

**Evaluation of the Concrete Operational Stage.** Piaget was correct that school-age children approach many problems in more organized, rational ways than preschoolers. But disagreement continues over whether this difference occurs because of *continuous* improvement in logical skills or *discontinuous* restructuring of children's thinking (as Piaget's stage idea assumes). Many researchers think that both types of change may be involved (Andrews & Halford, 2011; Barrouillet & Gaillard, 2011b; Case, 1998; Mascolo & Fischer, 2015).

During the school years, children apply logical schemes to many more tasks. In the process, their thought seems to change qualitatively—toward a more comprehensive grasp of the underlying principles of logical thought. Piaget himself recognized this possibility in evidence for gradual mastery of conservation and other tasks. So perhaps some blend of Piagetian and information-processing ideas holds the greatest promise for explaining cognitive development in middle childhood.

## Ask yourself

**CONNECT** Explain how advances in perspective taking and understanding of symbols contribute to school-age children's improved ability to draw and use maps.

**APPLY** Nine-year-old Adrienne spends many hours helping her father build furniture in his woodworking shop. How might this experience facilitate Adrienne's advanced performance on Piagetian seriation problems?

**REFLECT** Which aspects of Piaget's description of the concrete operational child do you accept? Which do you doubt? Explain, citing research evidence.

## Information Processing

**9.9** Describe gains in executive function and memory in middle childhood, along with factors that influence children's progress.

**9.10** Describe the school-age child's theory of mind and capacity to engage in self-regulation.

**9.11** Discuss current perspectives on teaching reading and mathematics to elementary school children.

In contrast to Piaget's focus on overall cognitive change, the information-processing perspective examines separate aspects of thinking. As noted in our discussion of Case's theory, working-memory capacity continues to increase in middle childhood. And school-age children make strides in other facets of executive function, including control of attention and planning. Dramatic gains also occur in strategic memory and self-regulation. Each advance contributes vitally to academic learning.

## Executive Function

The school years are a time of continued development of the prefrontal cortex, which increases its connections with more distant parts of the brain. Myelination of neural fibers rises steadily, especially in the prefrontal cortex and in the corpus callosum, which connects the two cerebral hemispheres (Giedd et al., 2009; Smit et al., 2012). As interconnectivity between the prefrontal cortex and other brain areas strengthens, the prefrontal cortex becomes a more effective "executive," overseeing the integrated functioning of neural networks.

Consequently, executive function undergoes marked improvement (Xu et al., 2013). Children handle increasingly difficult tasks that require the integration of working memory, inhibition, and flexible shifting of attention, which, in turn, support gains in planning, strategic thinking, and self-monitoring and self-correction of behavior.

Heritability evidence suggests considerable genetic contribution to executive function (Polderman et al., 2009; Young

© LAURA DWIGHT PHOTOGRAPHY

School-age children undergo marked gains in executive function. They can perform increasingly complex tasks—such as this science project on how flood plains are formed—that require the integration of working memory, inhibition, and flexible shifting of attention.

et al., 2009). And molecular genetic analyses are identifying specific genes related to severely deficient executive function components, such as inhibition and flexible thinking, which (as we will soon see) contribute to learning and behavior disorders, including attention-deficit hyperactivity disorder (ADHD) (refer to the Biology and Environment box on the following page).

But in both typically and atypically developing children, heredity combines with environmental contexts to influence executive function. In Chapter 3, we reviewed evidence indicating that prenatal teratogens can impair executive processes, including impulse control, attention, and planning. And as noted in Chapter 7, poverty, through chronic stress and poor parenting, undermines executive function. As we turn now to the development of executive function components in middle childhood, our discussion will confirm once more that supportive home and school experiences are essential for optimal development.

**Inhibition and Flexible Shifting.** During middle childhood, children become better at deliberately attending to relevant aspects of a task and inhibiting irrelevant responses. One way researchers study this increasing selectivity of attention is by introducing irrelevant stimuli into a task and seeing how well children attend to its central elements. Performance improves sharply between ages 6 and 10, with gains continuing throughout adolescence (Gomez-Perez & Ostrosky-Solis, 2006; Tabibi & Pfeffer, 2007; Vakil et al., 2009).

Older children are also better at flexibly shifting their attention in response to task requirements. When given rule-use tasks that require frequent switching of the rules used to sort picture cards containing conflicting cues (return to page 238 in Chapter 7 for an example), schoolchildren gain steadily with age in the complexity of rules they can keep in mind and in the speed and accuracy with which they shift between rules. Recall that flexible shifting benefits from gains in inhibition (enabling children to ignore rules not momentarily relevant) and

expansion of working memory (helping children keep multiple rules in mind).

In sum, selectivity and flexibility of attention become better controlled and more efficient over middle childhood (Carlson, Zelazo, & Faja, 2013). Children adapt their attention more quickly in the face of increasingly complex distractors—skills that contribute to more organized, strategic approaches to challenging tasks.

**Working Memory.** As Case's theory emphasizes, working memory profits from increased efficiency of thinking. Time needed to process information on a wide variety of cognitive tasks declines rapidly between ages 6 and 12 in diverse cultures, likely due to myelination and enhanced connectivity among regions of the cerebral cortex (Kail & Ferrer, 2007; Kail et al., 2013). A faster thinker can hold on to and operate on more information at once. Still, individual differences in working-memory capacity exist, and they are of particular concern because they predict intelligence test scores and academic achievement in many subjects (DeMarie & Lopez, 2014).

Children with persistent learning difficulties in reading and math are often deficient in working memory (Alloway et al., 2009). Observations of elementary school children with limited working memories revealed that they often failed at school assignments that made heavy memory demands (Gathercole, Lamont, & Alloway, 2006). They could not follow complex instructions, lost their place in tasks with multiple steps, and frequently gave up before finishing their work. The children struggled because they could not hold in mind sufficient information to complete assignments.

Compared to their economically advantaged agemates, children from poverty-stricken families are more likely to score low on working-memory tasks. In one study, years of childhood spent in poverty predicted reduced working memory in early adulthood (Evans & Schamberg, 2009). Childhood neurobiological measures of stress—elevated blood pressure and stress hormone levels, including cortisol—largely explained this poverty-working-memory association. Chronic stress, as we saw in Chapter 4, can impair brain structure and function, especially in the prefrontal cortex and its connections with the hippocampus, which govern working-memory capacity.

About 15 percent of children have very low working-memory scores, and the majority struggle in school (Holmes, Gathercole, & Dunning, 2010). Scaffolding in which parents and teachers modify tasks to reduce memory load is essential so these children can learn. Effective approaches include communicating in short sentences with familiar vocabulary, repeating task instructions, breaking complex tasks into manageable parts, and encouraging children to use external memory aids—for example, lists of useful spellings while writing or number lines while doing math (Gathercole & Alloway, 2008).

**Training Executive Function.** An increasing number of studies confirm that children's executive function skills can be improved through training, with benefits for both academic

## Biology and Environment

### Children with Attention-Deficit Hyperactivity Disorder

While the other fifth graders worked quietly at their desks, Calvin squirmed, dropped his pencil, looked out the window, and fiddled with his shoelaces. “Hey Joey,” he yelled across the room, “wanna play ball after school?” But the other children weren’t eager to play with Calvin, who was physically awkward and failed to follow the rules of the game. He had trouble taking turns at bat and, in the outfield, looked elsewhere when the ball came his way. Calvin’s desk was a chaotic mess. He often lost pencils, books, and other school materials, and he had difficulty remembering assignments and due dates.

#### Symptoms of ADHD

Calvin is one of about 5 percent of U.S. school-age children with **attention-deficit hyperactivity disorder (ADHD)**, which involves inattention, impulsivity, and excessive motor activity resulting in academic and social problems (American Psychiatric Association, 2013; Goldstein, 2011). Boys are diagnosed two to three times as often as girls. However, many girls with ADHD seem to be overlooked, either because their symptoms are less flagrant or because of a gender bias: A difficult, disruptive boy is more likely to be referred for treatment (Faraone, Biederman, & Mick, 2006).

Children with ADHD cannot stay focused on a task that requires mental effort for more than a few minutes. They often act impulsively, ignoring social rules and lashing out with hostility when frustrated. Many, though not all, are *hyperactive*, exhausting parents and teachers and irritating other children with their excessive motor activity. For a child to be diagnosed with ADHD, these symptoms must have appeared before age 12 as a persistent problem.

Because of their difficulty concentrating, children with ADHD score lower in IQ than other children, though the difference is mostly accounted for by a small subgroup with substantially below-average scores (Biederman et al., 2012). Researchers agree that deficient executive function underlies ADHD symptoms. Children with ADHD are impaired in ability to

inhibit distracting behaviors and irrelevant information and score low in working-memory capacity (Antshel, Hier, & Barkley, 2015). Consequently, they have difficulty with sustained attention, planning, memory, reasoning, and problem solving in academic and social situations and often fail to manage frustration and intense emotion.

#### Origins of ADHD

ADHD runs in families and is highly heritable: Identical twins share it more often than fraternal twins (Freitag et al., 2010). Children with ADHD show abnormal brain functioning, including reduced electrical and blood-flow activity and structural abnormalities in the prefrontal cortex and in other areas involved in attention, inhibition of behavior, and other aspects of motor control (Mackie et al., 2007). Also, the brains of children with ADHD grow more slowly and are about 3 percent smaller in overall volume, with a thinner cerebral cortex, than the brains of unaffected age-mates (Narr et al., 2009; Shaw et al., 2007). Several genes that disrupt functioning of the neurotransmitters serotonin (involved in inhibition and self-control) and dopamine (required for effective cognitive processing) have been implicated in the disorder (Akutagava-Martins et al., 2013).

At the same time, ADHD is associated with environmental factors. Prenatal teratogens—such as tobacco, alcohol, illegal drugs, and environmental pollutants—are linked to inattention and hyperactivity. Furthermore, children with ADHD are more likely to have parents with psychological disorders and to come from homes where family stress is high (Law et al., 2014). These circumstances often intensify the child’s preexisting difficulties.

This child frequently engages in disruptive behaviors at school. Children with ADHD have great difficulty staying on task and often act impulsively, ignoring social rules.

#### Treating ADHD

Calvin’s doctor eventually prescribed stimulant medication, the most common treatment for ADHD. These drugs seem to increase activity in the prefrontal cortex, thereby reducing impulsivity and hyperactivity and improving attention for most children who take them (Connor, 2015).

By itself, drug treatment is insufficient for helping children compensate for inattention and impulsivity in everyday situations. So far, the most effective treatments combine medication with interventions that provide training in executive function skills and that model and reinforce appropriate academic and social behavior (Smith & Shapiro, 2015; Tamm, Nakonezny, & Hughes, 2014).

Family intervention is also vital. Inattentive, hyperactive children strain the patience of parents, who are likely to react punitively and inconsistently—a child-rearing style that strengthens defiant, aggressive behavior. In fact, in 50 to 75 percent of cases, these two sets of behavior problems occur together (Goldstein, 2011).

ADHD is usually a lifelong disorder. Adults with ADHD continue to need help in structuring their environments, regulating negative emotion, selecting appropriate careers, and understanding their condition as a biological deficit rather than a character flaw.

© WAVEBREAK MEDIA LTD./WAVEBREAK MEDIA LTD./CORBIS

These fourth graders take a break from school work to meditate, a practice that requires focused attention and reflection. Mindfulness training such as meditation leads to gains in executive function, school grades, prosocial behavior, and positive peer relations.

achievement and social competence (Müller & Kerns, 2015). Both direct and indirect training approaches are effective.

To enhance control of attention and working memory, researchers often embed direct training in interactive computer games. In one investigation, 10-year-olds with learning difficulties who played a game providing working-memory training four times a week for eight weeks showed substantially greater improvement in working-memory capacity, IQ, and spelling and math achievement over age-mates who played less often or did not play at all (Alloway, Bibile, & Lau, 2013). Working memory, IQ, and spelling gains were still evident eight months after the training ended.

Executive function can also be enhanced indirectly, by increasing children's participation in activities—such as exercise—known to promote it (see page 300). Another indirect method attracting growing interest is *mindfulness training*, which—similar to meditation- and yoga-based exercises for adults—encourages children to focus attention on their current thoughts, feelings, and sensations, without judging them. For example, children might be asked to attend to their own breathing or to manipulate an object held behind their backs while noticing how it feels (Zelazo & Lyons, 2012). If their attention wanders, they are told to bring it back to the current moment. Mindfulness training leads to gains in executive function, school grades, prosocial behavior, and positive peer relations in school-age children (Schonert-Reichl & Lawlor, 2010; Schonert-Reichl et al., 2015). The sustained attention and reflection that mindfulness requires seem to help children avoid snap judgments, distracting thoughts and emotions, and impulsive behavior.

**Planning.** Planning on multistep tasks improves over the school years. On tasks with multiple parts, older children make decisions about what to do first and what to do next in a more orderly fashion. By the end of middle childhood, children engage in *advance planning*—evaluating an entire sequence of steps to

see if it will get them to their goal (Tecwyn, Thorpe, & Chappell, 2014). Nine- and 10-year-olds can project ahead, predicting how early steps in their plan will affect success at later steps and adjust their overall plan accordingly.

As Chapter 7 revealed, children learn much about planning from collaborating with more expert planners. With age, they take more responsibility in these joint endeavors, such as suggesting planning strategies and organizing task materials. The demands of school tasks—and parents' and teachers' explanations of how to plan—contribute to gains in school-age children's planning.

But adult-controlled activities may rob children of opportunities to plan. In one study, researchers videotaped small groups of first and second graders devising plays they would perform for their class (Baker-Sennett, Matusov, & Rogoff, 2008). Some groups were child-led, whereas others were led by adult volunteers. Child-led groups engaged in extensive planning, brainstorming themes and working out the details of their plays. But when adults planned the play in advance, the children spent most of their time in nonplanning pursuits, such as rehearsing lines. The adults missed a rich opportunity to scaffold planning by turning over responsibility for it to the children and guiding and supporting, as needed.

## Memory Strategies

As attention improves, so do *memory strategies*, deliberate mental activities we use to store and retain information. When Lizzie had a list of things to learn, such as the state capitals of the United States, she immediately used **rehearsal**—repeating the information to herself. Soon after, a second strategy becomes common: **organization**—grouping related items together (for example, all state capitals in the same part of the country), an approach that greatly improves recall (Schneider, 2002).

Perfecting memory strategies requires time and effort. Eight-year-old Lizzie rehearsed in a piecemeal fashion. After being given the word *cat* in a list of items, she said, “Cat, cat, cat.” But 10-year-old Joey combined previous words with each new item, saying, “Desk, man, yard, cat, cat.” This active, cumulative approach, in which neighboring words create contexts for each other that trigger recall, yields much better memory (Lehman & Hasselhorn, 2012). And whereas Lizzie often organized by everyday association (hat—head, carrot—rabbit), Joey grouped items *taxonomically*, based on common properties (clothing, food, animals), thus using fewer categories—an efficient procedure yielding dramatic memory gains (Bjorklund et al., 1994). Furthermore, Joey often combined several strategies—for example, organizing items, stating the category names, and finally rehearsing (Schwenck, Bjorklund, & Schneider, 2007). The more strategies children apply simultaneously, the better they remember.

By the end of middle childhood, children start to use **elaboration**—creating a relationship, or shared meaning, between two or more pieces of information that do not belong

to the same category. For example, to learn the words *fish* and *pipe*, you might generate the verbal statement or mental image, “The fish is smoking a pipe” (Schneider & Pressley, 1997). This highly effective memory technique, which requires considerable effort and space in working memory, becomes increasingly common in adolescence.

Because organization and elaboration combine items into *meaningful chunks*, they permit children to hold onto much more information and, as a result, further expand working memory. In addition, when children link a new item to information they already know, they can *retrieve* it easily by thinking of other items associated with it. As we will see, this also contributes to improved memory during the school years.

## Knowledge and Memory

During middle childhood, children’s general knowledge base, or *semantic memory*, grows larger and becomes organized into increasingly elaborate, hierarchically structured networks. This rapid growth of knowledge helps children use strategies and remember (Schneider, 2002). Knowing more about a topic makes new information more meaningful, so it is easier to store and retrieve.

To investigate this idea, researchers classified fourth graders as either experts or novices in knowledge of soccer and then gave both groups lists of soccer and nonsoccer items to learn. Experts remembered far more items on the soccer list (but not on the nonsoccer list) than novices. And during recall, the experts’ listing of items was better organized, as indicated by clustering of items into categories (Schneider & Bjorklund, 1992). This superior organization at retrieval suggests that highly knowledgeable children organize information in their area of expertise with little or no effort. Consequently, experts can devote more working-memory resources to using recalled information for reasoning and problem solving.

But knowledge is not the only important factor in children’s strategic memory processing. Children who are expert in an area are usually highly motivated. As a result, they not only acquire knowledge more quickly but also *actively use what they know* to add more. In contrast, academically unsuccessful children fail to ask how previously stored information can clarify new material. This, in turn, interferes with the development of a broad knowledge base (Schneider & Bjorklund, 1998). So extensive knowledge and use of memory strategies support each other.

## Culture, Schooling, and Memory Strategies

A repeated finding is that people in village cultures who have little formal schooling do not use or benefit from instruction in memory strategies because they see no practical reason to use these techniques (Rogoff, 2003). Tasks requiring children to recall isolated pieces of information, which are common in classrooms, strongly motivate use of memory strategies.

© KAREL NAVARRO/AP IMAGES

Children in a shanty town on the outskirts of Lima use laptops provided by the Peruvian government. Societal modernization—access to contemporary resources for communication and literacy—is broadly associated with improved cognitive performance.

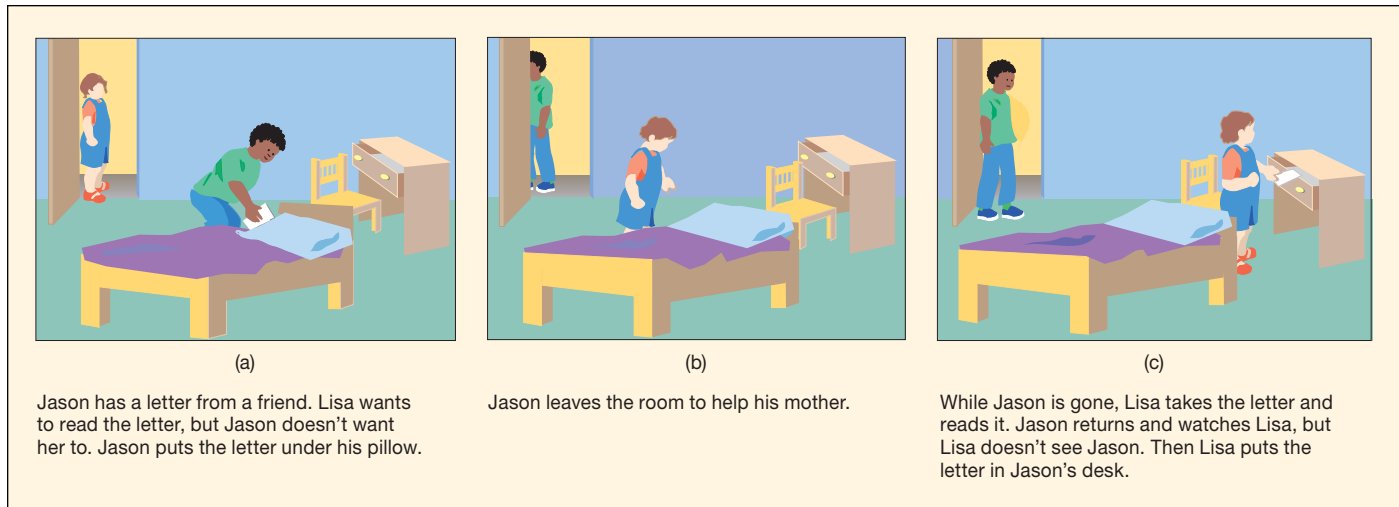

*Societal modernization*—indicated by the presence of books, writing tablets, electricity, radio, TV, and other economically advantageous resources in homes—is broadly associated with performance on cognitive tasks commonly given to children in industrialized nations. In an investigation in which researchers rated towns in Belize, Kenya, Nepal, and American Samoa for degree of modernization, Belize and American Samoa exceeded Kenya and Nepal (Gauvain & Munroe, 2009). Modernization predicted both extent of schooling and 5- to 9-year-olds’ cognitive scores on a memory test plus an array of other measures.

In sum, the development of memory strategies is not just a product of a more competent information-processing system. It also depends on task demands, schooling, and cultural circumstances.

## The School-Age Child’s Theory of Mind

During middle childhood, children’s *theory of mind*, or set of ideas about mental activities, becomes more elaborate and refined. Recall from Chapter 7 that this awareness of thought is often called *metacognition*. Children’s improved ability to reflect on their own mental life is another reason that their thinking advances.

Unlike preschoolers, who view the mind as a passive container of information, older children regard it as an active, constructive agent that selects and transforms information (Astington & Hughes, 2013). Consequently, they have a much better understanding of cognitive processes and the impact of psychological factors on performance. For example, with age, elementary school children become increasingly aware of effective memory strategies and why they work (Alexander et al., 2003). And

**FIGURE 9.5** A second-order false-belief task. After relating the story in the sequence of pictures, the researcher asks a second-order false-belief question: “Where does Lisa think Jason will look for the letter? Why?” Around age 7, children answer correctly—that Lisa thinks Jason will look under his pillow because Lisa doesn't know that Jason saw her put the letter in the desk. (Adapted from Astington, Pelletier, & Homer, 2002.)

gradually they grasp relationships between mental activities—for example, that remembering is crucial for understanding and that understanding strengthens memory (Schwanenflugel, Henderson, & Fabricius, 1998).

Furthermore, school-age children's understanding of sources of knowledge expands. They realize that people can extend their knowledge not just by directly observing events and talking to others but also by making *mental inferences* (Miller, Hardin, & Montgomery, 2003). This grasp of inference enables knowledge of *false belief* to expand. In several studies, researchers told children complex stories involving one character's belief about a second character's belief. Then the children answered questions about what the first character thought the second character would do (see Figure 9.5). By age 6 to 7, children were aware that people form beliefs about other people's beliefs and that these second-order beliefs can be wrong!

Appreciation of *second-order false belief* enables children to pinpoint the reasons that another person arrived at a certain belief (Miller, 2009; Naito & Seki, 2009). Notice how it requires the ability to view a situation from at least two perspectives—that is, to reason simultaneously about what two or more people are thinking, a form of perspective taking called **recursive thought**. We think recursively when we make such statements as “*Lisa believes that Jason believes the letter is under his pillow, but that's not what Jason really believes; he knows the letter is in the desk.*”

The capacity for recursive thought greatly assists children in appreciating that people can harbor quite different interpretations of the same reality. For example, around ages 7 to 8, children realize that two people are likely to interpret the same event quite differently, regardless of the beliefs and biases they bring to the situation (Lalonde & Chandler, 2002). Indeed, school-age children's newfound awareness of varying viewpoints is so powerful that, at first, they overextend it (Lagattuta, Sayfan, &

Blattman, 2010). They often overlook the fact that people with different past experiences sometimes agree!

As with other cognitive attainments, schooling contributes to a more reflective, process-oriented view of mental activities. In school, teachers often call attention to the workings of the mind by asking children to remember mental steps, share points of view with peers, and evaluate their own and others' reasoning.

## Cognitive Self-Regulation

Although metacognition expands, school-age children frequently have difficulty putting what they know about thinking into action. They are not yet good at **cognitive self-regulation**, the process of continuously monitoring progress toward a goal, checking outcomes, and redirecting unsuccessful efforts. For example, Lizzie is aware that she should group items when memorizing and reread a complicated paragraph to make sure she understands it. But she does not always engage in these activities.

To study cognitive self-regulation, researchers sometimes look at the impact of children's awareness of memory strategies on how well they remember. By second grade, the more children know about memory strategies, the more they recall—a relationship that strengthens over middle childhood (DeMarie et al., 2004). And when children apply a strategy consistently, their knowledge of it strengthens, resulting in a bidirectional relationship between metacognition and strategy use that enhances self-regulation (Schlagmüller & Schneider, 2002).

Cognitive self-regulation develops gradually because monitoring and controlling task outcomes is highly demanding, requiring constant evaluation of effort and progress. Throughout elementary and secondary school, self-regulation predicts academic success (Zimmerman & Labuhn, 2012). Students who do

well in school know when they encounter obstacles to learning and take steps to address them—for example, by organizing the learning environment, reviewing confusing material, or seeking support from more expert adults or peers (Schunk & Zimmerman, 2013). This active, purposeful approach contrasts sharply with the passive orientation of students who achieve poorly.

Parents and teachers can foster self-regulation. In one study, researchers observed parents instructing their children on a problem-solving task during the summer before third grade. Parents who patiently pointed out important features of the task and suggested strategies had children who, in the classroom, more often discussed ways to approach problems and monitored their own performance (Stright et al., 2002). Explaining the effectiveness of strategies is particularly helpful because it provides a rationale for future action.

Children who acquire effective self-regulatory skills develop a sense of *academic self-efficacy*—confidence in their own ability, which supports future self-regulation (Zimmerman & Moylan, 2009). Unfortunately, some children receive messages from parents and teachers that seriously undermine their academic self-esteem and self-regulatory skills. We will consider these *learned-helpless* students, along with ways to help them, in Chapter 10.

## Applications of Information Processing to Academic Learning

Fundamental discoveries about the development of information processing have been applied to children's learning of reading and mathematics. Researchers are identifying the cognitive ingredients of skilled performance, tracing their development, and distinguishing good from poor learners by pinpointing differences in cognitive skills. They hope, as a result, to design teaching methods that will improve children's learning.

**Reading.** Reading makes use of many skills at once, taxing all aspects of our information-processing system. Joey and Lizzie must perceive single letters and letter combinations, translate them into speech sounds, recognize the visual appearance of many common words, hold chunks of text in working memory while interpreting their meaning, and combine the meanings of various parts of a text passage into an understandable whole. Because reading is so demanding, most or all of these skills must be done automatically. If one or more are poorly developed, they will compete for space in our limited working memories, and reading performance will decline.

As children make the transition from emergent literacy to conventional reading, *phonological awareness* (see page 244 in Chapter 7) continues to facilitate their progress. Other information-processing skills also contribute. Gains in processing speed foster children's rapid conversion of visual symbols into sounds (Moll et al., 2014). Visual scanning and discrimination play important roles and improve with reading experience (Rayner, Pollatsek, & Starr, 2003). Performing all these skills

efficiently releases working memory for higher-level activities involved in comprehending the text's meaning.

Until recently, researchers were involved in an intense debate over how to teach beginning reading. Those who took a **whole-language approach** argued that from the beginning, children should be exposed to text in its complete form—stories, poems, letters, posters, and lists. According to this view, as long as reading is kept whole and meaningful, children will be motivated to discover the specific skills they need. Other experts advocated a **phonics approach**, believing that children should first be coached on *phonics*—the basic rules for translating written symbols into sounds. Only after mastering these skills should they get complex reading material.

Many studies confirm that children learn best with a mixture of both approaches. In kindergarten, first, and second grades, teaching that includes phonics boosts reading scores, especially for children who lag behind in reading progress (Block, 2012; Brady, 2011). Learning letter-sound relationships enables children to *decode*, or decipher, words they have never seen before. Yet too much emphasis on basic skills may cause children to lose sight of the goal of reading: understanding. Children who read aloud fluently without registering meaning know little about effective metacognitive reading strategies—for example, that they must read more carefully if they will be tested than if they are reading for pleasure, that relating ideas in the text to personal experiences and general knowledge will deepen understanding, and that explaining a passage in their own words is a good way to assess comprehension. Teaching aimed at increasing awareness and use of reading strategies enhances reading performance from third grade on (Lonigan, 2015; McKeown & Beck, 2009).

**Mathematics.** Mathematics teaching in elementary school builds on and greatly enriches children's informal knowledge of number concepts and counting. Written notation systems and formal computational procedures enhance children's ability to represent numbers and compute. Over the early elementary school years, children acquire basic math facts through a combination of frequent practice, experimentation with diverse computational procedures (through which they discover faster, more accurate techniques), reasoning about number concepts, and teaching that conveys effective strategies. Eventually children retrieve answers automatically and apply this knowledge to more complex problems.

Arguments about how to teach mathematics resemble those in reading, pitting drill in computing against “number sense,” or understanding. Again, a blend of both approaches is most beneficial (Fuson, 2009). In learning basic math, poorly performing students use cumbersome, error-prone techniques or try to retrieve answers from memory too soon. They have not sufficiently experimented with strategies to see which are most effective and to reorganize their observations in logical, efficient ways—for example, noticing that multiplication problems involving the number 2 ( $2 \times 8$ ) are equivalent to addition doubles ( $8 + 8$ ). On tasks assessing their grasp of math concepts, their performance is weak (Clements & Sarama, 2012). This suggests

© LAURA DWIGHT PHOTOGRAPHY

This fourth grader uses paper cut in different sizes to clarify the concept of fractions. The most effective math teaching combines frequent practice with instruction emphasizing conceptual understanding.

that encouraging students to apply strategies and making sure they understand why certain strategies work well are essential for solid mastery of basic math.

A similar picture emerges for more complex skills, such as carrying in addition, borrowing in subtraction, and operating with decimals and fractions. Children taught by rote persistently make mistakes, following a “math rule” that they recall incorrectly because they do not understand it (Carpenter et al., 1999).

In one study, the more teachers emphasized conceptual knowledge, by having children actively construct meanings in word problems before practicing computation and memorizing math facts, the more children gained in math achievement from second to third grade (Staub & Stern, 2002). Children taught in this way draw on their solid knowledge of relationships between operations—for example, that the inverse of division is multiplication—to generate efficient, flexible procedures. And because they have been encouraged to estimate answers, if they go down the wrong track in computation, they are usually self-correcting. They also select math operations that are appropriate for problem contexts. They can solve a word problem (“Jesse spent \$3.45 for bananas, \$2.62 for bread, and \$3.55 for peanut butter. Can he pay for it all with a \$10 bill?”) quickly through estimation instead of exact calculation (De Corte & Verschaffel, 2006).

In Asian countries, students receive a variety of supports for acquiring mathematical knowledge and often excel at math computation and reasoning. Use of the metric system helps Asian children grasp place value. The consistent structure of number words in Asian languages (*ten-two* for 12, *ten-three* for 13) also makes this idea clear (Miura & Okamoto, 2003). And because Asian number words are shorter and more quickly pronounced, more digits can be held in working memory at once, increasing speed of thinking. Furthermore, Chinese parents provide their preschoolers with extensive practice in counting and computation—experiences that contribute to the superiority of Chinese over U.S. children’s math knowledge even before school entry (Siegler & Mu, 2008; Zhou et al., 2006). Finally, as we will see later in this chapter, compared with lessons in the United States, those in Asian classrooms devote more time to exploring math concepts and strategies and less to drill and repetition.

## Ask yourself

**CONNECT** Explain why gains in executive function are vital for mastery of reading and math in middle childhood.

**APPLY** Lizzie knows that if you have difficulty learning part of a task, you should devote extra attention to that part. But she plays each of her piano pieces from beginning to end instead of practicing the hard parts. What explains Lizzie’s failure to engage in cognitive self-regulation?

**REFLECT** In your elementary school math education, how much emphasis was placed on computational drill and how much on understanding concepts? How do you think that balance affected your interest and performance in math?

## Individual Differences in Mental Development

**9.12** Describe major approaches to defining and measuring intelligence.

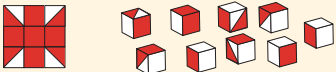

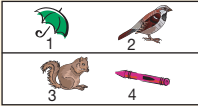

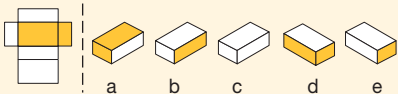

**9.13** Describe evidence indicating that both heredity and environment contribute to intelligence.

Around age 6, IQ becomes more stable than it was at earlier ages, and it correlates moderately with academic achievement, typically around .50 to .60. And children with higher IQs are more likely to attain higher levels of education and enter more prestigious occupations in adulthood (Deary et al., 2007). Because IQ predicts school performance and educational attainment, it often enters into educational decisions. Do intelligence tests accurately assess school-age children’s ability to profit from academic instruction? Let’s look closely at this controversial issue.

## Defining and Measuring Intelligence

Virtually all intelligence tests provide an overall score (the IQ), which represents *general intelligence*, or reasoning ability, along

with an array of separate scores measuring specific mental abilities. But intelligence is a collection of many capacities, not all of which are included on currently available tests (Carroll, 2005; Sternberg, 2008). Test designers use a complicated statistical technique called *factor analysis* to identify the various abilities that intelligence tests measure. It identifies which sets of test items cluster together, meaning that test-takers who do well on one item in a cluster tend to do well on the others. Distinct clusters are called *factors*, each of which represents an ability. See Figure 9.6 for items typically included in intelligence tests for children.

TYPICAL VERBAL ITEMS	
<b>Vocabulary</b>	Tell me what <i>carpet</i> means.
<b>General Information</b>	What day of the week comes right after Thursday?
<b>Verbal Comprehension</b>	Why do we need police officers?
<b>Similarities</b>	How are a ship and a train alike?
<b>Quantitative Reasoning</b>	If a \$60 jacket is 25% off, how much does it cost?
TYPICAL PERCEPTUAL- AND SPATIAL-REASONING ITEMS	
<b>Block Design</b>	Make these blocks look just like the picture. 
<b>Picture Concepts</b>	Choose one object from each row to make a group of objects that goes together. 
<b>Spatial Visualization</b>	Which of the boxes on the right can be made from the pattern on the left? 
TYPICAL WORKING-MEMORY ITEMS	
<b>Digit Span</b>	Repeat these digits in the same order. Now repeat these digits (a similar series) backward. <b>2, 6, 4, 7, 1, 8</b>
<b>Letter-Number Sequencing</b>	Repeat these numbers and letters, first giving the numbers, then the letters, each in correct sequence. <b>8 G 4 B 5 N 2</b>
TYPICAL PROCESSING-SPEED ITEM	
<b>Symbol Search</b>	If the shape on the left is the same as any of those on the right, mark YES. If the shape is not the same, mark NO. Work as quickly as you can without making mistakes.  YES NO

**FIGURE 9.6** Test items like those on commonly used intelligence tests for children. The verbal items emphasize culturally loaded, fact-oriented information. The perceptual- and spatial-reasoning, working-memory, and processing-speed items emphasize aspects of information processing and are assumed to assess more biologically based skills.

Although *group-administered* intelligence tests are available that permit large numbers of students to be tested at once, intelligence is most often assessed with *individually administered* tests, which are best suited for identifying highly intelligent children and diagnosing children with learning problems. During an individually administered test, a well-trained examiner not only considers the child's answers but also observes the child's behavior, noting such reactions as attention to and interest in the tasks and wariness of the adult. These observations provide insight into whether the test results accurately reflect the child's abilities. Two individual tests—the Stanford-Binet and the Wechsler—are used especially often.

The contemporary descendant of Alfred Binet's first successful intelligence test is the *Stanford-Binet Intelligence Scales*, Fifth Edition, for individuals from age 2 to adulthood. In addition to general intelligence, it assesses five intellectual factors: general knowledge, quantitative reasoning, visual-spatial processing, working memory, and basic information processing (such as speed of analyzing information). Each factor includes both a verbal mode and a nonverbal mode of testing, yielding 10 subtests in all (Roid, 2003; Roid & Pomplun, 2012). The nonverbal subtests, which do not require spoken language, are particularly useful when assessing individuals with limited English, hearing impairments, or communication disorders. The knowledge and quantitative reasoning factors emphasize culturally loaded, fact-oriented information, such as vocabulary and arithmetic problems. In contrast, the visual-spatial processing, working-memory, and basic information-processing factors are assumed to be less culturally biased (see the spatial visualization item in Figure 9.6).

The *Wechsler Intelligence Scale for Children (WISC-V)* is the fifth edition of a widely used test for 6- through 16-year-olds. It measures general intelligence and an array of intellectual factors, five of which are recommended for a comprehensive evaluation of a child's intellectual ability: verbal comprehension, visual-spatial reasoning, fluid reasoning (tapping ability to apply rules in reasoning and to detect conceptual relationships among objects), working memory, and processing speed (Weiss et al., 2015). The WISC-V was designed to downplay culture-dependent information, which is emphasized on only one factor (verbal comprehension). The goal is to provide a test that is as "culture-fair" as possible.

## Other Efforts to Define Intelligence

As we have seen, mental tests now tap important aspects of information processing. In line with this trend, some researchers have combined the mental-testing approach to defining intelligence with the information-processing approach. They believe that once we identify the processing skills that separate individuals who test well from those who test poorly, we will know more about how to intervene to improve performance.

Processing speed, assessed in terms of reaction time on diverse cognitive tasks, is moderately related to IQ (Coyle, 2013; Li et al., 2004). Individuals whose nervous systems function

more efficiently, permitting them to take in more information and manipulate it quickly, have an edge in intellectual skills. And not surprisingly, executive function strongly predicts general intelligence (Brydges et al., 2012; Schweizer, Moosebrugger, & Goldhammer, 2006). We have seen that the components of executive function are vital for success on a great many cognitive tasks.

Individual differences in intelligence, however, are not entirely due to causes within the child. Throughout this book, we have seen how cultural and situational factors affect children's thinking. Robert Sternberg has devised a comprehensive theory that regards intelligence as a product of both inner and outer forces.

**Sternberg's Triarchic Theory.** As Figure 9.7 shows, Sternberg's (2005, 2008, 2013) **triarchic theory of successful intelligence** identifies three broad, interacting intelligences: (1) *analytical intelligence*, or information-processing skills; (2) *creative intelligence*, the capacity to solve novel problems; and (3) *practical intelligence*, application of intellectual skills in everyday situations. Intelligent behavior involves balancing all three intelligences to achieve success in life according to one's personal goals and the requirements of one's cultural community.

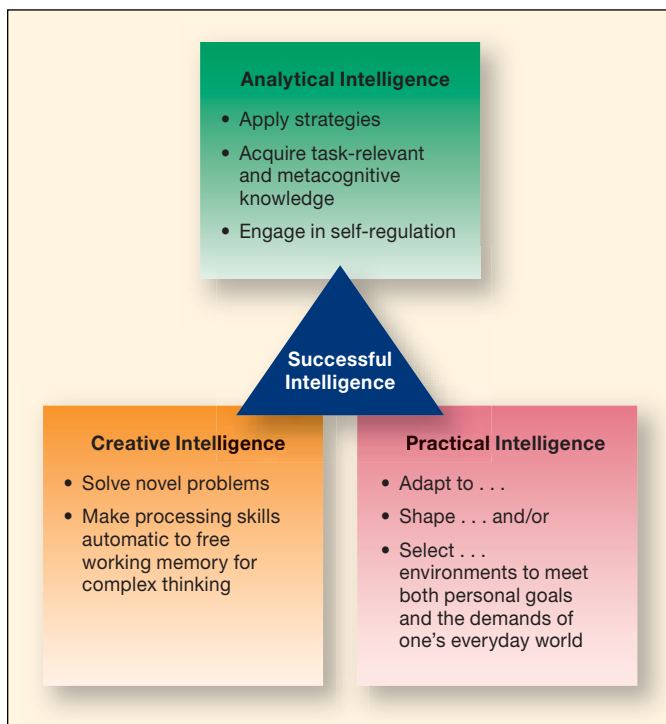

**Analytical Intelligence.** *Analytical intelligence* consists of the information-processing skills that underlie all intelligent acts: executive function, strategic thinking, knowledge acquisi-

tion, and cognitive self-regulation. But on intelligence tests, processing skills are used in only a few of their potential ways, resulting in far too narrow a view of intelligent behavior.

**Creative Intelligence.** In any context, success depends not only on processing familiar information but also on generating useful solutions to new problems. People who are *creative* think more skillfully than others when faced with novelty. Given a new task, they apply their information-processing skills in exceptionally effective ways, rapidly making these skills automatic so that working memory is freed for more complex aspects of the situation. Consequently, they quickly move to high-level performance. Although all of us are capable of some creativity, only a few individuals excel at generating novel solutions.

**Practical Intelligence.** Finally, intelligence is a *practical*, goal-oriented activity aimed at *adapting to, shaping, or selecting environments*. Intelligent people skillfully *adapt* their thinking to fit with both their desires and the demands of their everyday worlds. When they cannot adapt to a situation, they try to *shape*, or change, it to meet their needs. If they cannot shape it, they *select* new contexts that better match their skills and goals. Practical intelligence reminds us that intelligent behavior is never culture-free. Children with certain life histories do well at the behaviors required for success on intelligence tests and adapt easily to the testing conditions and tasks. Others, with different backgrounds, may misinterpret or reject the testing context. Yet such children often display sophisticated abilities in daily life—for example, telling stories, engaging in complex artistic activities, or interacting skillfully with other people.

The triarchic theory highlights the complexity of intelligent behavior and the limitations of current intelligence tests in assessing that complexity. For example, out-of-school, practical forms of intelligence are vital for life success and help explain why cultures vary widely in the behaviors they regard as intelligent (Sternberg, 2011). In villages in Kenya, children regarded as cognitively competent are highly knowledgeable about how to use herbal medicines to treat disease. Among the Yup'ik Eskimo people of central Alaska, intelligent youths are those with expert hunting, gathering, navigating, and fishing skills (Hein, Reich, & Grigorenko, 2015). And U.S. Cambodian, Filipino, Vietnamese, and Mexican immigrant parents asked to describe an intelligent first grader emphasized noncognitive capacities—motivation, self-management, and social skills (Okagaki & Sternberg, 1993). According to Sternberg, intelligence tests, devised to predict achievement in school, do not capture the intellectual strengths that many children acquire through informal learning experiences in their cultural communities.

**FIGURE 9.7** Sternberg's triarchic theory of successful intelligence. People who behave intelligently balance three interrelated intelligences—analytical, creative, and practical—to achieve success in life, defined by their personal goals and the requirements of their cultural communities.

**Gardner's Theory of Multiple Intelligences.** In yet another view of how information-processing skills underlie intelligent behavior, Howard Gardner's (1983, 1993, 2011) **theory of multiple intelligences** defines intelligence in terms of distinct sets of processing operations that permit individuals to engage in

**TABLE 9.1**  
**Gardner's Multiple Intelligences**

INTELLIGENCE	PROCESSING OPERATIONS	END-STATE PERFORMANCE POSSIBILITIES
Linguistic	Sensitivity to the sounds, rhythms, and meaning of words and the functions of language	Poet, journalist
Logico-mathematical	Sensitivity to, and capacity to detect, logical or numerical patterns; ability to handle long chains of logical reasoning	Mathematician
Musical	Ability to produce and appreciate pitch, rhythm (or melody), and aesthetic quality of the forms of musical expressiveness	Instrumentalist, composer
Spatial	Ability to perceive the visual–spatial world accurately, to perform transformations on those perceptions, and to re-create aspects of visual experience in the absence of relevant stimuli	Sculptor, navigator
Bodily-kinesthetic	Ability to use the body skillfully for expressive as well as goal-directed purposes; ability to handle objects skillfully	Dancer, athlete
Naturalist	Ability to recognize and classify all varieties of animals, minerals, and plants	Biologist
Interpersonal	Ability to detect and respond appropriately to the moods, temperaments, motivations, and intentions of others	Therapist, salesperson
Intrapersonal	Ability to discriminate complex inner feelings and to use them to guide one's own behavior; knowledge of one's own strengths, weaknesses, desires, and intelligences	Person with detailed, accurate self-knowledge

Sources: Gardner, 1983, 1993, 2011.

a wide range of culturally valued activities. Dismissing the idea of general intelligence, Gardner proposes at least eight independent intelligences (see Table 9.1).

Gardner believes that each intelligence has a unique neurological basis, a distinct course of development, and different expert, or “end-state,” performances. At the same time, he emphasizes that a lengthy process of education is required to transform any raw potential into a mature social role (Gardner, 2011). Cultural values and learning opportunities affect the extent to which a child's intellectual strengths are realized and the ways they are expressed.

© JEFF GREENBERG/ROBERT HARDING

According to Gardner, people are capable of at least eight distinct intelligences. Through a project aimed at improving sea turtle nesting habitats, these children expand and enrich their naturalist intelligence.

Gardner's list of abilities has yet to be firmly grounded in research. Neurological evidence for the independence of his abilities is weak. Some exceptionally gifted individuals have abilities that are broad rather than limited to a particular domain (Piiro, 2007). And research with mental tests suggests that several of Gardner's intelligences (linguistic, logico-mathematical, and spatial) have at least some features in common. Nevertheless, Gardner calls attention to several intelligences not tapped by IQ scores.

For example, Gardner's interpersonal and intrapersonal intelligences include a set of skills for accurately perceiving, reasoning about, and regulating emotion that has become known as *emotional intelligence*. Among school-age children and adolescents, measures of emotional intelligence are positively associated with self-esteem, empathy, prosocial behavior, cooperation, leadership skills, and academic performance and negatively associated with internalizing and externalizing problems (Brackett, Rivers, & Salovey, 2011; Ferrando et al., 2011). These findings have increased teachers' awareness that providing classroom lessons that coach students in emotional abilities can improve their adjustment.

## Explaining Individual and Group Differences in IQ

When we compare individuals in terms of academic achievement, years of education, and occupational status, it quickly becomes clear that certain sectors of the population are advantaged over others. In trying to explain these differences,

researchers have compared the IQ scores of ethnic and SES groups. American black children and adolescents score, on average, 10 to 12 IQ points below American white children. Although the difference has been shrinking over the past several decades, a substantial gap remains (Nisbett, 2009; Nisbett et al., 2012). Hispanic children fall midway between black and white children, and Asian Americans score slightly higher than their white counterparts—about 3 points (Ceci, Rosenblum, & Kumpf, 1998).

The gap between middle- and low-SES children—about 9 points—accounts for some of the ethnic differences in IQ, but not all (Brooks-Gunn et al., 2003). Of course, IQ varies greatly *within* each ethnic and SES group, and minority top performers are typically indistinguishable from top performers in the white majority. Still, these group differences are large enough and of serious enough consequence that they cannot be ignored.

Beginning in the 1970s, the IQ nature–nurture controversy escalated after psychologist Arthur Jensen (1969) claimed that heredity is largely responsible for individual, ethnic, and SES variations in intelligence—a position others asserted as well (Herrnstein & Murray, 1994; Jensen, 2001; Rushton & Jensen, 2006, 2010). These contentions prompted an outpouring of research studies and responses, including ethical challenges reflecting deep concern that the conclusions would fuel social prejudices. Let’s look closely at some important evidence.

**Nature versus Nurture.** In Chapter 2, we introduced the *heritability estimate*. The most powerful evidence on the heritability of IQ involves twin comparisons. The IQ scores of identical twins (who share all their genes) are more similar than those of fraternal twins (who are genetically no more alike than ordinary siblings). On the basis of this and other kinship evidence, researchers estimate that about half the differences in IQ among children can be traced to their genetic makeup.

Recall, however, that heritabilities risk overestimating genetic influences and underestimating environmental influences. Although these measures offer convincing evidence that genes contribute to IQ, disagreement persists over how large a role heredity plays. As we saw in Chapter 2, the heritability of children’s intelligence rises with parental education and income—conditions that enable children to realize their genetic potential. And heritability estimates do not reveal the complex processes through which genes and experiences influence intelligence as children develop.

Adoption studies offer a wider range of information. When young children are adopted into caring, stimulating homes, their IQs rise substantially compared with the IQs of nonadopted children who remain in economically deprived families (Hunt, 2011). But adopted children benefit to varying degrees. In one investigation, children of two extreme groups of biological mothers—those with IQs below 95 and those with IQs above 120—were adopted at birth by parents who were well above average in income and education. During the school years, the children of the low-IQ biological mothers scored above average in IQ. But they did not do as well as children of high-IQ biological mothers placed in similar adoptive families (Loehlin, Horn, &

Willerman, 1997). Adoption research confirms that heredity and environment jointly contribute to IQ.

Adoption studies also shed light on the black–white IQ gap. In two investigations, African-American children adopted into economically well-off white homes during the first year of life scored high on intelligence tests, attaining mean IQs of 110 and 117 by middle childhood (Moore, 1986; Scarr & Weinberg, 1983). The IQ gains of black children “reared in the culture of the tests and schools” are consistent with a wealth of evidence that poverty severely depresses the intelligence of ethnic minority children (Nisbett et al., 2012).

Dramatic gains in IQ from one generation to the next offer additional support for the conclusion that, given new experiences and opportunities, members of oppressed groups can move far beyond their current test performance. See the Cultural Influences box on the following page to learn about the Flynn effect.

**Cultural Influences.** A controversial question raised about ethnic differences in IQ has to do with whether they result from *test bias*. If a test samples knowledge and skills that not all groups of children have had equal opportunity to learn, or if the testing situation impairs the performance of some groups but not others, then the resulting score is a biased, or unfair, measure.

Some experts claim that because IQ predicts academic achievement equally well for majority and minority children, intelligence tests are fair to both groups. The tests, they say, represent success in the common culture (Edwards & Oakland, 2006; Jensen, 2002). Others believe that lack of exposure to certain communication styles and knowledge, along with negative stereotypes about the test-taker’s ethnic group, can undermine children’s performance (McKown, 2013; Sternberg, 2005).

**Language and Communication Styles.** Ethnic minority families often foster unique language skills that do not match the expectations of most classrooms and testing situations.

The majority of African-American children enter school speaking African-American English. Their home discourse differs from standard English, on which school learning is based.

## Cultural Influences

### The Flynn Effect: Massive Generational Gains in IQ

After gathering IQ scores from diverse nations that had either military mental testing or frequent testing of other large, representative samples, James Flynn (1999, 2007) reported a finding so consistent and intriguing that it became known as the **Flynn effect**: IQs have increased steadily from one generation to the next. Evidence for the Flynn effect now exists for 30 nations (Nisbett et al., 2012). This dramatic *secular trend* in intelligence test performance holds for industrialized and developing nations, both genders, and individuals varying in ethnicity and SES (Ang, Rodgers, & Wänström, 2010; Rodgers & Wänström, 2007). Gains are greatest on tests of spatial reasoning—tasks often assumed to be “culture-fair” and, therefore, mostly genetically based.

The amount of increase depends on extent of societal modernization (see page 311 to review). Among European and North American nations that modernized by the early twentieth century, IQ gains have been about 3 points per decade (Flynn, 2007). IQ has continued to increment at that pace in England and the United States, but gains have slowed in certain nations with especially favorable economic

and social conditions, such as Norway and Sweden (Schneider, 2006; Sundet, Barlaug, & Torjussen, 2004).

Among nations that modernized later, around the mid-twentieth century (such as Argentina), IQ gains tend to be larger, as much as 5 to 6 points per decade (Flynn & Rossi-Casé, 2011). And nations that began to modernize in the late twentieth century (Caribbean countries, Kenya, Sudan) show even greater increments, especially in spatial reasoning (Daley et al., 2003; Khaleefa, Sulman, & Lynn, 2009). The degree of societal modernity possible today is far greater than it was a century ago.

Diverse aspects of modernization probably underlie the better reasoning ability of each successive generation. These include improved education, health, and technology (TV, computers, the Internet); more cognitively demanding jobs and leisure activities (reading, chess, video games); a generally more stimulating world; and greater test-taking motivation.

As developing nations continue to advance in IQ, they are projected to catch up with the industrialized world by the end of the twenty-first century (Nisbett et al., 2012). Large, envi-

© LAURA DWIGHT PHOTOGRAPHY

Dramatic generational gains in IQ may result, in part, from greater participation by each successive generation in cognitively stimulating leisure activities.

ronmentally induced gains in IQ over time present a major challenge to the assumption that black–white and other ethnic variations in IQ are genetic.

African-American English is a complex, rule-governed dialect used by most African Americans in the United States (Craig & Washington, 2006). Nevertheless, it is often inaccurately viewed as a deficient form of standard American English rather than as different from it.

The majority of African-American children entering school speak African-American English, though they vary in the extent to which they use it. Greater users tend to come from low-SES families, who quickly learn that the language they bring from home is devalued in school. Teachers frequently try to “correct” or eliminate their use of African-American English forms, replacing these with standard English (Washington & Thomas-Tate, 2009). Because their home discourse is distinctly different from the linguistic knowledge required to learn to read, children who speak mostly African-American English in school generally progress slowly in reading and achieve poorly (Charity, Scarborough, & Griffin, 2004).

Many African-American children learn to flexibly shift between African-American English and standard English by

third grade. But those who continue to speak mostly their African-American dialect through the later grades—the majority of whom live in poverty and therefore have few opportunities outside of school for exposure to standard English—fall further behind in reading and in overall achievement (Washington & Thomas-Tate, 2009). These children have a special need for school programs that facilitate mastery of standard English while respecting and accommodating their home language in the classroom.

Research also reveals that many ethnic minority parents without extensive education prefer a *collaborative style of communication* when completing tasks with children. They work together in a coordinated, fluid way, each focused on the same aspect of the problem. This pattern of adult–child engagement has been observed in Native-American, Canadian Inuit, Hispanic, and Guatemalan Mayan cultures (Chavajay & Rogoff, 2002; Crago, Annahatak, & Ningiuruvik, 1993; Paradise & Rogoff, 2009). With increasing education, parents establish a *hierarchical style of communication*, like that of classrooms and

tests. The parent directs each child to carry out an aspect of the task, and children work independently (Greenfield, Suzuki, & Rothstein-Fish, 2006). This sharp discontinuity between home and school communication practices likely contributes to low-SES minority children's lower IQs and school performance.

**Knowledge.** Many researchers argue that IQ scores are affected by specific information acquired as part of majority-culture upbringing. Knowledge affects ability to reason effectively. In one study, researchers assessed black and white community college students' familiarity with vocabulary taken from items on an intelligence test. When verbal comprehension, similarities, and analogies items depended on words that the white students knew better, the whites scored higher than the blacks. When the same types of items involved words that the two groups knew equally well, the two groups did not differ (Fagan & Holland, 2007). Prior knowledge, not reasoning ability, fully explained ethnic differences in performance.

Even nonverbal test items, such as spatial reasoning, depend on learning opportunities. For example, among children, adolescents, and adults alike, playing video games that require fast responding and mental rotation of visual images increases success on spatial test items (Uttal et al., 2013). Low-income minority children may lack opportunities to use games and objects that promote certain intellectual skills.

Furthermore, the sheer amount of time children spend in school predicts IQ. In comparisons of children of the same age who are in different grades, those who have been in school longer score higher in verbal intelligence—a difference that increases as the children advance further in school (Bedard & Dhuey, 2006). Taken together, these findings indicate that children's exposure to the knowledge and ways of thinking valued in classrooms has a sizable impact on their intelligence test performance.

**Stereotypes.** Imagine trying to succeed at an activity when the prevailing attitude is that members of your group are incompetent. **Stereotype threat**—the fear of being judged on the basis of a negative stereotype—can trigger anxiety that interferes with performance. Mounting evidence confirms that stereotype threat undermines test taking in children and adults (McKown & Strambler, 2009). For example, researchers gave African-American, Hispanic-American, and European-American 6- to 10-year-olds verbal tasks. Some children were told that the tasks were “not a test.” Others were told they were “a test of how good children are at school problems”—a statement designed to induce stereotype threat in the ethnic minority children. Among children who were aware of ethnic stereotypes (such as “black people aren't smart”), African Americans and Hispanics performed far worse in the “test” condition than in the “not a test” condition (McKown & Weinstein, 2003). European-American children, in contrast, performed similarly in both conditions.

From third grade on, children become increasingly conscious of ethnic stereotypes, and those from stigmatized groups

are especially mindful of them. By early adolescence, many low-SES minority students start to devalue doing well in school, saying it is not important to them (Killen, Rutland, & Ruck, 2011). Self-protective disengagement, sparked by stereotype threat, may be responsible. This weakening of motivation can have serious, long-term consequences. Research shows that self-discipline—effort and delay of gratification—predicts school performance, as measured by report card grades, better than IQ does (Duckworth, Quinn, & Tsukayama, 2012).

**Reducing Cultural Bias in Testing.** Although not all experts agree, many acknowledge that IQ scores can underestimate the intelligence of children from ethnic minority groups. A special concern exists about incorrectly labeling minority children as slow learners and assigning them to remedial classes, which are far less stimulating than regular school experiences. To avoid this danger, test scores need to be combined with assessments of children's adaptive behavior—their ability to cope with the demands of their everyday environments. The child who does poorly on an intelligence test yet plays a complex game on the playground or figures out how to rewire a broken TV is unlikely to be intellectually deficient.

In addition, flexible testing procedures enhance minority children's performance. In an approach called **dynamic**

© LAURA DWIGHT PHOTOGRAPHY

This teacher uses dynamic assessment, tailoring instruction to students' individual needs—an approach that reveals what each child can learn with social support.

**assessment**, an innovation consistent with Vygotsky's zone of proximal development, the adult introduces purposeful teaching into the testing situation to find out what the child can attain with social support (Robinson-Zañartu & Carlson, 2013).

Research shows that children's receptivity to teaching and capacity to transfer what they have learned to novel problems contribute substantially to gains in test performance (Haywood & Lidz, 2007). In one study, first graders diverse in SES and ethnicity participated in dynamic assessment in which they were asked to solve a series of unfamiliar math equations that increased in difficulty, such as  $\_\_ + 1 = 4$  (easier) and  $3 + 6 = 5 + \_\_$  (difficult). When a child could not solve an equation, an adult provided increasingly explicit teaching until the child either succeeded or still had trouble, in which case the session ended. Beyond static IQ-like measures of children's verbal, math, and reasoning abilities, performance during dynamic assessment strongly predicted end-of-year scores on a test of math story problems, which children usually find highly challenging (Seethaler et al., 2012). Dynamic assessment seemed to evoke skills and understandings that children readily applied to a very different and demanding type of math.

Cultural bias in testing can also be reduced by countering the negative impact of stereotype threat. In one approach, researchers encouraged African-American students to affirm their self-worth by writing a short essay about their most important values—for example, a close friendship or a self-defining skill. This self-affirmation intervention was just as successful in boosting end-of-term grades of poorly performing middle school students as it was for students doing moderately well in school (see Figure 9.8).

In view of its many problems, should intelligence testing in schools be suspended? Most experts reject this solution. Without testing, important educational decisions would be based only on subjective impressions, perhaps increasing discriminatory placement of minority children. Intelligence tests are useful when interpreted carefully by psychologists and educators who are sensitive to cultural influences on test performance. And despite their limitations, IQ scores continue to be fairly accurate measures of school learning potential for the majority of Western children.

## Ask yourself

**CONNECT** Explain how dynamic assessment is consistent with Vygotsky's zone of proximal development and with scaffolding. (See Chapter 7, page 235.)

**APPLY** Josefina, a Hispanic fourth grader, does well on homework assignments. But when her teacher announces, "It's time for a test to see how much you've learned," Josefina usually does poorly. How might stereotype threat explain this inconsistency?

**REFLECT** Do you think that intelligence tests are culturally biased? What observations and evidence influenced your conclusions?

**FIGURE 9.8** Impact of a self-affirmation intervention on African-American middle-school students' end-of-term grade-point average. In the fall, several hundred students were randomly assigned to either a self-affirmation intervention, in which they wrote brief essays about the personal meaning of their most important values, or a control condition, in which they wrote essays about why their least important values might be meaningful to someone else. African-American students experiencing the self-affirmation condition earned substantially higher end-of-term course grades than did controls; poorly performing and moderately performing students benefitted similarly. White students' grades were unaffected, indicating that the treatment succeeded by lessening the negative impact of stereotype threat on the African Americans. (Based on Cohen, Garcia, & Master, 2006.)

## Language Development

**9.14** Describe changes in school-age children's vocabulary, grammar, and pragmatics, and cite the advantages of bilingualism for development.

Vocabulary, grammar, and pragmatics continue to develop in middle childhood, though less obviously than at earlier ages. In addition, children's attitude toward language undergoes a fundamental shift: They develop language awareness.

## Vocabulary and Grammar

During the elementary school years, vocabulary increases four-fold, eventually reaching comprehension of 40,000 words. On average, children learn about 20 new words each day, a rate of growth greater than in early childhood. In addition to the word-learning strategies discussed in Chapter 7, school-age children add to their vocabularies by analyzing the structure of complex words. From *happy* and *decide*, they quickly derive the meanings of *happiness* and *decision* (Larsen & Nippold, 2007). They also figure out many more word meanings from context (Nagy & Scott, 2000).

As at earlier ages, children benefit from conversing with more expert speakers. But because written language contains a far more diverse and complex vocabulary than spoken language, reading contributes enormously to vocabulary growth. Avid readers are exposed to more than 4 million words per year, average readers to 600,000 words, and children who rarely read to just 50,000 words (Anderson, Wilson, & Fielding, 1988). By second to third grade, reading comprehension and reading habits strongly predict later vocabulary size into high school (Cain & Oakhill, 2011).

As their knowledge becomes better organized, older school-age children think about and use words more precisely: In addition to the verb *fall*, for example, they also use *topple*, *tumble*, and *plummet* (Berman, 2007). Word definitions also illustrate this change. Five- and 6-year-olds offer concrete descriptions referring to functions or appearance—*knife*: “when you’re cutting carrots.” By the end of elementary school, synonyms and explanations of categorical relationships appear—for example, *knife*: “something you could cut with. A saw is like a knife. It could also be a weapon” (Uccelli & Pan, 2013). This advance reflects older children’s ability to deal with word meanings on an entirely verbal plane. They can add new words to their vocabulary simply by being given a definition.

School-age children’s more reflective and analytical approach to language permits them to appreciate the multiple meanings of words—to recognize, for example, that many words, such as *cool* or *neat*, have psychological as well as physical meanings: “Cool shirt!” or “That movie was really neat!” This grasp of double meanings permits 8- to 10-year-olds to comprehend subtle metaphors, such as “sharp as a tack” and “spilling the beans” (Nippold, Taylor, & Baker, 1996; Wellman & Hickling, 1994). It also leads to a change in children’s humor. Riddles and puns that alternate between different meanings of a key word are common: “Hey, did you take a bath?” “Why, is one missing?”

### LOOK and LISTEN

Record examples of 8- to 10-year-olds’ humor, or examine storybooks for humor aimed at second through fourth graders. Does it require a grasp of the multiple meanings of words?

Mastery of complex grammatical constructions also improves. For example, English-speaking children use the passive voice more frequently, and they more often extend it from an abbreviated form (“It broke”) into full statements (“The glass was broken by Mary”) (Tomasello, 2006). Another grammatical achievement of middle childhood is advanced understanding of infinitive phrases—the difference between “John is eager to please” and “John is easy to please” (Berman, 2007; Chomsky, 1969). Like gains in vocabulary, appreciation of these subtle grammatical distinctions is supported by an improved ability to analyze and reflect on language.

## Pragmatics

A more advanced theory of mind—in particular, the capacity for recursive thought—enables children to understand and use increasingly subtle, indirect expressions of meaning with age. Around age 8, children begin to grasp irony and sarcasm (Glenwright & Pexman, 2010). After Rena prepared a dish for dinner that Joey didn’t like, he quipped sarcastically, “Oh boy, my favorite!” Notice how this remark requires the speaker to consider at least two perspectives simultaneously—in Joey’s case, his mother’s desire to serve a particular dish despite his objection, expressed through a critical comment with a double meaning.

Furthermore, as a result of improved memory, ability to take the perspective of listeners, and conversations with adults about past experiences, children’s narratives increase in organization, detail, and expressiveness. A typical 4- or 5-year-old’s narrative states what happened: “We went to the lake. We fished and waited. Paul caught a huge catfish.” Six- and 7-year-olds add orienting information (time, place, participants) and connectives (“next,” “then,” “so,” “finally”) that lend coherence to the story. Gradually, narratives lengthen into a *classic form* in which events not only build to a high point but resolve: “After Paul reeled in the catfish, Dad cleaned and cooked it. Then we ate it all up!” And evaluative comments rise dramatically, becoming common by age 8 to 9: “The catfish tasted great. Paul was so proud!” (Melzi & Schick, 2013; Ukrainetz et al., 2005).

Because children pick up the narrative styles of significant adults in their lives, their narratives vary widely across cultures. For example, instead of the *topic-focused style* of most European-American children, who describe an experience from beginning to end, African-American children often use a

© TAMPA BAY TIMES/MELISSA LYTTLE/THE IMAGE WORKS

In families who regularly eat meals together, children are advanced in language and literacy development. Mealtimes offer many opportunities to relate complex, extended personal stories.

*topic-associating style* in which they blend several similar experiences. One 9-year-old related having a tooth pulled, then described seeing her sister's tooth pulled, next told how she had removed one of her own baby teeth, and concluded, "I'm a pullin-teeth expert . . . call me, and I'll be over" (McCabe, 1997, p. 164). Like adults in their families and communities, African-American children are more attuned to keeping their listeners interested than to relating a linear sequence of events. They often embellish their narratives by including fictional elements and many references to characters' motives and intentions (Gorman et al., 2011). As a result, African-American children's narratives are usually longer and more complex than those of white children.

The ability to generate clear oral narratives enhances reading comprehension and prepares children for producing longer, more explicit written narratives. In families who regularly eat meals together, children are advanced in language and literacy development, perhaps because mealtimes offer many opportunities to relate personal stories (Snow & Beals, 2006).

## Learning Two Languages

Joey and Lizzie speak only one language—English, their native tongue. Yet throughout the world, many children grow up *bilingual*, and some acquire more than two languages. An estimated 22 percent of U.S. children—11.2 million in all—speak a language other than English at home (U.S. Census Bureau, 2015d).

**Bilingual Development.** Children can become bilingual in two ways: (1) by acquiring both languages at the same time in early childhood or (2) by learning a second language after acquiring the first. Children of bilingual parents who teach them both languages in infancy and early childhood separate the language systems early on and attain early language milestones according to a typical timetable (Hoff et al., 2012). When preschool and school-age children from immigrant families acquire a second language after they already speak the language of their cultural heritage, the time required to master the second language to the level of native-speaking age-mates varies greatly, from 1 to 5 or more years (MacWhinney, 2015; Pérez & Hunter, 2015). Influential factors include child motivation, knowledge of the first language (which supports mastery of the second), and quality of communication and of literacy experiences in both languages at home and at school.

As with first-language development, a *sensitive period* for second-language development exists. Mastery must begin sometime in childhood for most second-language learners to attain full proficiency (Hakuta, Bialystok, & Wiley, 2003). But a precise age cutoff for a decline in second-language learning has not been established. Rather, a continuous age-related decrease from childhood to adulthood occurs.

Children who become fluent in two languages develop denser synaptic connections in areas of the left hemisphere devoted to language. And compared to monolinguals, bilinguals

show greater activity in these areas and in the prefrontal cortex during linguistic tasks, likely due to the high executive-processing demands of controlling two languages (Costa & Sebastián-Gallés, 2014). Because both languages are always active, bilingual speakers must continuously decide which one to use in particular social situations, resisting attention to the other.

This increase in executive processing has diverse cognitive benefits as bilinguals acquire more efficient executive function skills and apply them to other tasks (Bialystok, 2011). Bilingual children and adults outperform others on tests of inhibition, sustained and selective attention, flexible shifting, analytical reasoning, concept formation, and false-belief understanding (Bialystok, Craik, & Luk, 2012; Carlson & Meltzoff, 2008). They are also advanced in certain aspects of language awareness, such as detection of errors in grammar, meaning, and conventions of conversation (responding politely, relevantly, and informatively). And children transfer their phonological awareness skills in one language to the other, especially if the two languages share phonological features and letter-sound correspondences, as Spanish and English do (Bialystok, 2013; Siegal, Iozzi, & Surian, 2009). These capacities, as noted earlier, enhance reading achievement.

**Bilingual Education.** The advantages of bilingualism provide strong justification for bilingual education programs in schools. In Canada, about 7 percent of elementary school students are enrolled in *language immersion programs*, in which English-speaking children are taught entirely in French for several years. This strategy succeeds in developing children who are proficient in both languages and who, by grade 6, achieve as well in reading, writing, and math as their counterparts in the regular English program (Genesee & Jared, 2008; Lyster & Genesee, 2012).

In the United States, fierce disagreement exists over how best to educate dual language learning children. Some believe that time spent communicating in the child's native tongue detracts from English-language achievement. Other educators, committed to developing minority children's native language while fostering mastery of English, note that providing instruction in the native tongue lets minority children know that their heritage is respected. It also prevents inadequate proficiency in both languages. Minority children who gradually lose the first language as a result of being taught the second end up limited in both languages (McCabe et al., 2013). This circumstance leads to severe academic difficulties and is believed to contribute to the high rates of school failure and dropout among low-SES Hispanic young people, who make up over 70 percent of the U.S. language-minority population.

At present, public opinion and educational practice favor English-only instruction. Many U.S. states have passed laws declaring English to be their official language, creating conditions in which schools have no obligation to teach minority students in languages other than English. Where bilingual education exists, usually its goal is to transition students to English-only

© CHRISTINA KENNEDY/PHOTODISC

The child on the left, a native Spanish speaker, benefits from an English–Spanish bilingual classroom, which sustains her native language while she masters English. And her native-English-speaking classmate has the opportunity to begin learning Spanish!

instruction as soon as possible (Wright, 2013). Yet in classrooms where both languages are integrated into the curriculum, minority children are more involved in learning and acquire the second language more easily—gains that result in better academic achievement (Guglielmi, 2008). In contrast, when teachers speak only in a language that children can barely understand, minority children display frustration, boredom, and escalating academic difficulties (Paradis, Genesee, & Crago, 2011). This downward spiral in achievement is greatest in high-poverty schools, where resources to support the needs of language-minority children are scarce.

Supporters of U.S. English-only education often point to the success of Canadian language immersion programs, in which classroom lessons are conducted in the second language. But Canadian parents enroll their children in immersion classrooms voluntarily, and students in those programs are native speakers of the dominant language of their region. Furthermore, teaching in the child's native language is merely delayed, not ruled out. For U.S. non-English-speaking minority children, whose native languages are not valued by the larger society, a different strategy is necessary—one that promotes children's native-language and -literacy skills while they learn English.

## Ask yourself

**CONNECT** How can bilingual education promote ethnic minority children's cognitive and academic development?

**APPLY** After soccer practice, 10-year-old Shana remarked, "I'm wiped out!" Megan, her 5-year-old sister, responded, "What did'ya wipe out?" Explain Shana's and Megan's different understandings.

**REFLECT** Considering research on bilingualism, what changes would you make in your second-language learning, and why?

## Learning in School

- 9.15** Describe the influence of educational philosophies on children's motivation and academic achievement.
- 9.16** Discuss the role of teacher–student interaction and grouping practices in academic achievement.
- 9.17** Under what conditions is placement of children with learning difficulties in regular classrooms successful?
- 9.18** Describe the characteristics of gifted children and current efforts to meet their educational needs.
- 9.19** How well-educated are U.S. children compared with children in other industrialized nations?

Evidence cited throughout this chapter indicates that schools are vital forces in children's cognitive development. How do schools exert such a powerful influence? Research looking at schools as complex social systems, varying in educational philosophies, teacher–student relationships, and larger cultural context, provides important insights. As you read about these topics, refer to Applying What We Know on the following page, which summarizes characteristics of high-quality education in elementary school.

## Educational Philosophies

Teachers' educational philosophies play a major role in children's learning. Two philosophical approaches have received most research attention. They differ in what children are taught, the way they are believed to learn, and how their progress is evaluated.

**Traditional versus Constructivist Classrooms.** In a **traditional classroom**, the teacher is the sole authority for knowledge, rules, and decision making. Students are relatively passive—listening, responding when called on, and completing teacher-assigned tasks. Their progress is evaluated by how well they keep pace with a uniform set of standards for their grade.

A **constructivist classroom**, in contrast, encourages students to *construct* their own knowledge. Although constructivist approaches vary, many are grounded in Piaget's theory, which views children as active agents who reflect on and coordinate their own thoughts rather than absorbing those of others. A glance inside a constructivist classroom reveals richly equipped learning centers, small groups and individuals solving self-chosen problems, and a teacher who guides and supports in response to children's needs. Students are evaluated by considering their progress in relation to their own prior development.

In the United States, the pendulum has swung back and forth between these two views. In the 1960s and early 1970s, constructivist classrooms gained in popularity. Then, as concern arose over the academic progress of children and youths, classrooms returned to traditional instruction—a style that has become increasingly pronounced as a result of the 2001 No Child Left Behind Act, followed by its 2015 replacement, the Every Child

## Applying what we Know

### Signs of High-Quality Education in Elementary School

CLASSROOM CHARACTERISTICS	SIGNS OF QUALITY
Physical setting	Space is divided into richly equipped activity centers—for reading, writing, playing math or language games, exploring science, working on construction projects, using computers, and engaging in other academic pursuits. Spaces are used flexibly for individual and small-group activities and whole-class gatherings.
Curriculum	The curriculum helps children both achieve academic standards and make sense of their learning. Subjects are integrated so that children apply knowledge in one area to others. The curriculum is implemented through activities responsive to children's interests, ideas, and everyday lives, including their cultural backgrounds.
Daily activities	Teachers provide challenging activities that include opportunities for small-group and independent work. Groupings vary in size and makeup of children, depending on the activity and on children's learning needs. Teachers encourage cooperative learning and guide children in attaining it.
Interactions between teachers and children	Teachers foster each child's progress and use intellectually engaging strategies, including posing problems, asking thought-provoking questions, discussing ideas, and adding complexity to tasks. They also demonstrate, explain, coach, and assist in other ways, depending on each child's learning needs.
Evaluations of progress	Teachers regularly evaluate children's progress through written observations and work samples, which they use to enhance and individualize teaching. They help children reflect on their work and decide how to improve it. They also seek information and perspectives from parents on how well children are learning and include parents' views in evaluations.
Relationship with parents	Teachers forge partnerships with parents. They hold periodic conferences and encourage parents to visit the classroom anytime, to observe and volunteer.

Succeeds Act. These policies, by placing heavy pressure on teachers and school administrators to improve achievement test scores, have narrowed the curricular focus in many schools to preparing students to take such tests (Kew et al., 2012).

Although older elementary school children in traditional classrooms have a slight edge in achievement test scores, constructivist settings are associated with many other benefits—gains in critical thinking, greater social and moral maturity, and more positive attitudes toward school (DeVries, 2001; Rathunde & Csikszentmihalyi, 2005; Walberg, 1986). And as noted in Chapter 7, when teacher-directed instruction is emphasized in preschool and kindergarten, it actually undermines motivation and achievement, especially in low-SES children.

**Recent Philosophical Directions.** Recent approaches to education, grounded in Vygotsky's sociocultural theory, capitalize on the rich social context of the classroom to spur children's learning. In these **social-constructivist classrooms**, children participate in a wide range of challenging activities with teachers and peers, with whom they jointly construct understandings. As children acquire knowledge and strategies through working together, they become competent, contributing members of their classroom community and advance in cognitive and social development (Bodrova & Leong, 2007; Lourenço, 2012). Vygotsky's emphasis on the social origins of complex mental activities has inspired the following educational themes:

- *Teachers and children as partners in learning.* A classroom rich in both teacher–child and child–child collaboration transfers culturally valued ways of thinking to children.
- *Experiences with many types of symbolic communication in meaningful activities.* As children master reading, writing, and mathematics, they become aware of their culture's communication systems, reflect on their own thinking, and bring it under voluntary control. Can you identify research presented earlier in this chapter that supports this theme?
- *Teaching adapted to each child's zone of proximal development.* Assistance that both responds to current understandings and encourages children to take the next step helps ensure that each child makes the best progress possible.

According to Vygotsky, besides teachers, more expert peers can spur children's learning, as long as they adjust the help they provide to fit the less mature child's zone of proximal development. Consistent with this idea, mounting evidence confirms that peer collaboration promotes development only under certain conditions. A crucial factor is **cooperative learning**, in which small groups of classmates work toward common goals—by considering one another's ideas, appropriately challenging one another, providing sufficient explanations to correct misunderstandings, and resolving differences of opinion on the basis of reasons and evidence. When teachers explain, model, and have children role-play how to work together effectively, cooperative

© LAURA DWIGHT PHOTOGRAPHY

Fourth graders work together to complete an assignment. Cooperative learning enhances children's complex reasoning skills as well as their enjoyment of learning and academic achievement.

learning among heterogeneous peers results in more complex reasoning, greater enjoyment of learning, and achievement gains across a wide range of subjects (Jadallah et al., 2011; Webb et al., 2008).

## Teacher–Student Interaction and Grouping Practices

Elementary school students describe good teachers as caring, helpful, and stimulating—behaviors associated with gains in motivation, achievement, and positive peer relations (Hughes & Kwok, 2006, 2007; Hughes, Zhang, & Hill, 2006; O'Connor & McCartney, 2007). But too many U.S. teachers—especially those in schools with many students from low-income families—emphasize repetitive drill over higher-level thinking, such as grappling with ideas and applying knowledge to new situations (Valli, Croninger, & Buese, 2012). This focus on low-level skills becomes increasingly pronounced over the school year as state-mandated achievement testing draws nearer.

Of course, teachers do not interact in the same way with all children. Well-behaved, high-achieving students typically get more encouragement and praise, whereas unruly students have more conflicts with teachers and receive more criticism from them (Henricsson & Rydell, 2004). Warm, low-conflict teacher–student relationships have an especially strong impact on the academic self-esteem, achievement, and social behavior of low-SES minority students and other children at risk for learning difficulties (Hughes, 2011; Hughes et al., 2012; Spilt et al., 2012). But overall, higher-SES students—who tend to be higher-achieving and to have fewer learning and behavior problems—have more sensitive and supportive relationships with teachers (Jerome, Hamre, & Pianta, 2008).

Unfortunately, once teachers' attitudes toward students are established, they can become more extreme than is warranted by

students' behavior. Of special concern are **educational self-fulfilling prophecies**: Children may adopt teachers' positive or negative views and start to live up to them. This effect is especially strong when teachers emphasize competition and publicly compare children, regularly favoring the best students (Weinstein, 2002).

Teacher expectations have a greater impact on low-achieving than high-achieving students (McKown, Gregory, & Weinstein, 2010). When a teacher is critical, high achievers can fall back on their history of success. Low-achieving students' sensitivity to self-fulfilling prophecies can be beneficial when teachers believe in them. But biased teacher judgments are usually slanted in a negative direction. In one study, African-American and Hispanic elementary school students taught by high-bias teachers (who expected them to do poorly) showed substantially lower end-of-year achievement than their counterparts taught by low-bias teachers (McKown & Weinstein, 2008). Recall our discussion of *stereotype threat*. A child in the position of confirming a negative stereotype may respond with especially intense anxiety and reduced motivation, amplifying a negative self-fulfilling prophecy.

In many schools, students are assigned to *homogeneous* groups or classes in which children of similar ability levels are taught together. Homogeneous grouping can be a potent source of self-fulfilling prophecies. Low-group students—who as early as first grade are more likely to be low-SES, minority, and male—get more drill on basic facts and skills, engage in less discussion, and progress at a slower pace. Gradually, they decline in self-esteem and motivation and fall further behind in achievement (Lleras & Rangel, 2009; Worthy, Hungerford-Kresser, & Hampton, 2009).

Unfortunately, widespread SES and ethnic segregation in U.S. schools consigns large numbers of low-SES, minority students to a form of schoolwide homogeneous grouping. Refer to the Social Issues: Education box on the following page to find out how magnet schools foster heterogeneous learning contexts, thereby reducing achievement differences between SES and ethnic groups.

## Teaching Children with Special Needs

We have seen that effective teachers flexibly adjust their teaching strategies to accommodate students with a wide range of characteristics. These adjustments are especially challenging at the very low and high ends of the ability distribution. How do schools serve children with special learning needs?

**Children with Learning Difficulties.** U.S. legislation mandates that schools place children who require special supports for learning in the “least restrictive” (as close to normal as possible) environments that meet their educational needs. In **inclusive classrooms**, students with learning difficulties learn alongside typical students in the regular educational setting for all or part of the school day—a practice designed to prepare them for participation in society and to combat prejudices against individuals

## Social Issues: Education

### Magnet Schools: Equal Access to High-Quality Education

Each school-day morning, Emma leaves her affluent suburban neighborhood, riding a school bus 20 miles to a magnet school in an impoverished, mostly Hispanic inner-city neighborhood. In her fifth-grade class, she settles into a science project with her friend, Maricela, who lives in the local neighborhood. For the first hour of the day, the children use a thermometer, ice water, and a stopwatch to determine which of several materials is the best insulator, recording and graphing their data. Throughout the school, which specializes in innovative math and science teaching, students diverse in SES and ethnicity learn side-by-side.

Despite the 1954 U.S. Supreme Court *Brown v. Board of Education* decision ordering schools to desegregate, school integration receded over the 1990s as federal courts canceled their integration orders and returned this authority to states and cities. Since 2000, the racial divide in American education has improved only modestly (Stroub & Richards, 2013). When minority students attend ethnically mixed schools, they typically do so with other minorities.

U.S. schools in inner-city, low-income neighborhoods are vastly disadvantaged in funding and therefore in educational opportunities, largely because public education is primarily supported by local property taxes. Consequently, in inner-city segregated neigh-

borhoods, dilapidated school buildings; inexperienced teachers; outdated, poor-quality educational resources; and school cultures that fail to encourage strong teaching are widespread (Condrón, 2013). The negative impact on student achievement is severe.

Magnet schools offer a solution. In addition to the usual curriculum, they emphasize a specific area of interest—such as performing arts, math and science, or technology. Families outside the school neighborhood are attracted to magnet schools (hence the name) by their rich academic offerings. Often magnets are located in low-income, minority areas, where they serve the neighborhood student population. Other students, who apply and are admitted by lottery, are bussed in—many from well-to-do city and suburban neighborhoods. In another model, all students—including those in the surrounding neighborhood—must apply. In either case, magnet schools are voluntarily desegregated.

Do magnet schools enhance minority student achievement? A Connecticut study com-

paring students enrolled in magnet schools with those whose lottery numbers were not drawn and who therefore attended other city schools confirmed that the magnet students showed greater gains in reading and math achievement over a two-year period (Bifulco, Cobb, & Bell, 2009). These outcomes were strongest for low-SES, ethnic minority students.

By high school, the higher-achieving peer environments of ethnically diverse schools encourage more students to pursue higher education (Franklin, 2012). In sum, magnet schools are a promising approach to overcoming the negative forces of SES and ethnic isolation in American schools.

A magnet-school teacher receives hugs from her first-grade students at a party celebrating news that she is a finalist for Texas Elementary Teacher of the Year. Magnet schools typically attract students diverse in ethnicity and SES because of their rich academic offerings and innovative teaching.

with disabilities. Largely as the result of parental pressures, an increasing number of students experience *full inclusion*—full-time placement in regular classrooms.

Students with *mild intellectual disability* are sometimes integrated into inclusive classrooms. Typically, their IQs fall between 55 and 70, and they also show problems in adaptive behavior, or skills of everyday living (American Psychiatric Association, 2013). But the largest number designated for inclusion—5 to 10 percent of school-age children—have **learning disabilities**, great difficulty with one or more aspects of learning, usually reading. As a result, their achievement is considerably behind what would be expected on the basis of their IQ. Often these deficits express themselves in other ways—for example, as deficiencies in processing speed, attention, and working memory,

which depress both intelligence and achievement test scores (Cornoldi et al., 2014). The problems of students with learning disabilities cannot be traced to any obvious physical or emotional difficulty or to environmental disadvantage. Instead, deficits in brain functioning are involved (Waber, 2010). In many instances, the cause is unknown.

Although some students benefit academically from inclusion, many do not. Achievement gains depend on both the severity of the disability and the support services available (Downing, 2010). Furthermore, children with disabilities are often rejected by regular-classroom peers. Students with intellectual disability are overwhelmed by the social skills of their classmates; they cannot interact adeptly in a conversation or game. And the processing deficits of some students with learning disabilities lead

© ELLEN B. SENISI

In this inclusive first-grade classroom, a teacher encourages special-needs students' active participation. They are likely to do well if they receive support from a special education teacher and if their regular classroom teacher minimizes comparisons and promotes positive peer relations.

to problems in social awareness and responsiveness (Nowicki, Brown, & Stepien, 2014).

Does this mean that students with special needs cannot be served in regular classrooms? Not necessarily. Often these children do best when they receive instruction in a resource room for part of the day and in the regular classroom for the remainder (McLeskey & Waldron, 2011). In the resource room, a special education teacher works with students on an individual and small-group basis. Then, depending on their progress, children join typically developing classmates for different subjects and amounts of time.

Special steps must to be taken to promote peer relations in inclusive classrooms. Peer tutoring experiences in which teachers guide typical students in supporting the academic progress of classmates with learning difficulties lead to friendly interaction, improved peer acceptance, and achievement gains (Mastropieri et al., 2013). And when teachers prepare their class for the arrival of a student with special needs, inclusion may foster emotional sensitivity and prosocial behavior among regular classmates.

**Gifted Children.** Some children are **gifted**, displaying exceptional intellectual strengths. An IQ score above 130 is the standard definition of giftedness based on intelligence test performance (Pfeiffer & Yermish, 2014). High-IQ children have an exceptional capacity to solve challenging academic problems. Yet recognition that intelligence tests do not sample the entire range of human mental skills has led to an expanded conception of giftedness.

**Creativity and Talent.** Creativity is the ability to produce work that is *original yet appropriate*—something others have not thought of that is useful in some way (Kaufman & Sternberg, 2007). A child with high potential for creativity can be designated as gifted. Tests of creative capacity tap **divergent thinking**—the generation of multiple and unusual possibilities

when faced with a task or problem. Divergent thinking contrasts sharply with **convergent thinking**, which involves arriving at a single correct answer and is emphasized on intelligence tests (Guilford, 1985).

Because highly creative children (like high-IQ children) are often better at some tasks than others, a variety of tests of divergent thinking are available (Runco, 1992; Torrance, 1988). A verbal measure might ask children to name uses for common objects (such as a newspaper). A figural measure might ask them to create drawings based on a circular motif (see Figure 9.9). A “real-world problem” measure requires students to suggest solutions to everyday problems. Responses can be scored for the number of ideas generated and their originality.

Yet critics point out that these measures are poor predictors of creative accomplishment in everyday life because they tap only one of the complex cognitive contributions to creativity (Plucker & Makel, 2010). Also involved are defining new and important problems, evaluating divergent ideas, choosing the most promising, and calling on relevant knowledge to understand and solve problems (Lubart, Georgsdottir, & Besançon, 2009).

Consider these ingredients, and you will see why people usually demonstrate creativity in only one or a few related areas. Partly for this reason, definitions of giftedness have been extended to include **talent**—outstanding performance in a specific field. Case studies reveal that excellence in such endeavors as creative writing, mathematics, science, music, visual arts, athletics, and leadership has roots in specialized interests and skills that first appear in childhood (Moran & Gardner, 2006). Highly

**FIGURE 9.9 Responses of an 8-year-old who scored high on a figural measure of divergent thinking.** This child was asked to make as many pictures as she could from the circles on the page. The titles she gave her drawings, from left to right, are as follows: “Dracula,” “one-eyed monster,” “pumpkin,” “Hula-Hoop,” “poster,” “wheelchair,” “earth,” “stop-light,” “planet,” “movie camera,” “sad face,” “picture,” “beach ball,” “the letter O,” “car,” “glasses.” Tests of divergent thinking tap only one of the complex cognitive contributions to creativity. (Reprinted by permission of Laura E. Berk.)

talented children are biologically prepared to master their domain of interest, and they display a passion for doing so.

But talent must be nurtured. Studies of the backgrounds of talented children and highly accomplished adults often reveal warm, sensitive parents who provide a stimulating home life, are devoted to developing their child's abilities, and provide models of hard work. These parents are reasonably demanding but not overly ambitious (Winner, 2003). They arrange for caring teachers while the child is young and for more rigorous master teachers as the child's talent develops.

Although most are well-adjusted, many gifted children and adolescents experience social isolation, partly because their highly driven, independent styles leave them out of step with peers and partly because they enjoy solitude, which is necessary to develop their talents (Pfeiffer & Yermish, 2014). Still, gifted children desire gratifying peer relationships, and some—more often girls than boys—try to become better-liked by hiding their abilities (Reis, 2004).

Finally, whereas many talented youths become experts in their fields, few become highly creative. Rapidly mastering an existing field requires different skills than innovating in that field (Moran & Gardner, 2006). The world, however, needs both experts and creators.

**Educating the Gifted.** Debate about the effectiveness of school programs for the gifted typically focuses on factors irrelevant to giftedness—whether to provide enrichment in regular classrooms, pull children out for special instruction (the most common practice), or advance brighter students to a higher grade. Overall, gifted children fare well within each of these models, as long as special activities promote problem solving, critical thinking, and creativity (Guignard & Lubart, 2006).

Gardner's theory of multiple intelligences has inspired several model programs that provide enrichment to all students in diverse disciplines. Meaningful activities, each tapping a specific intelligence or set of intelligences, serve as contexts for assessing strengths and weaknesses and, on that basis, teaching new knowledge and original thinking (Gardner, 2000; Hoerr, 2004). For example, linguistic intelligence might be fostered through storytelling or playwriting; spatial intelligence through drawing, sculpting, or taking apart and reassembling objects; and kinesthetic intelligence through dance or pantomime.

Evidence is still needed on how well these programs nurture children's talents and creativity. But they have already succeeded in one way—by highlighting the strengths of some students who previously had been considered unexceptional or even at risk for school failure (Ford, 2012). Consequently, they may be especially useful in identifying talented low-SES, ethnic minority children, who are underrepresented in school programs for the gifted.

## How Well-Educated Are U.S. Children?

Our discussion of schooling has largely focused on how teachers can support the education of children. Yet many factors—both within and outside schools—affect children's learning. Societal

**FIGURE 9.10** Average mathematics scores of 15-year-olds by country. The Programme for International Student Assessment measured achievement in many nations around the world. In recent comparisons of countries' performance, the United States performed below the international average in math; in reading and science, its performance was about average. (Adapted from Programme for International Student Assessment, 2012.)

values, school resources, quality of teaching, and parental encouragement all play important roles. These multiple influences are especially apparent when schooling is examined in cross-cultural perspective.

In international studies of reading, mathematics, and science achievement, young people in China, Korea, and Japan are consistently top performers. Among Western nations, Canada, Finland, the Netherlands, and Switzerland are also in the top tier. But U.S. students typically perform at or below the international averages (see Figure 9.10) (Programme for International Student Assessment, 2012).

Why do U.S. students fall behind in academic accomplishment? According to international comparisons, instruction in the United States is less challenging, more focused on absorbing facts, and less focused on high-level reasoning and critical thinking than in other countries. A growing number of experts believe that U.S. educational policies directed at getting students to meet targeted goals on achievement tests by holding schools and teachers accountable for student performance have contributed to these trends (Darling-Hammond, 2010; Kew et al., 2012).

Furthermore, countries with large socioeconomic inequalities (such as the United States) rank lower in achievement, in part because low-SES children tend to live in less favorable family and neighborhood contexts (Condrón, 2013). But the United States is also far less equitable than top-achieving countries in the quality of education it provides its low-SES and ethnic minority students. U.S. teachers, for example, vary much more in training, salaries, and teaching conditions.

Finland is a case in point. Its nationally mandated curricula, teaching practices, and assessments are aimed at cultivating initiative, problem solving, and creativity—vital abilities needed for success in the twenty-first century. Finnish teachers are highly trained: They must complete several years of graduate-level education at government expense (Ripley, 2013). And Finnish education is grounded in equal opportunity for all—a policy that has nearly eliminated SES variations in achievement, despite

an influx of immigrant students from low-income families into Finnish schools over the two past decades.

In-depth research on learning environments in Asian nations, such as Japan, Korea, and Taiwan, also highlights social forces that foster strong student learning. Among these is cultural valuing of effort. Whereas American parents and teachers tend to regard native ability as the key to academic success, Japanese, Korean, and Taiwanese parents and teachers believe that all children can succeed academically as long as they try hard. Asian children, influenced by interdependent values, typically view striving to achieve as a moral obligation—part of their responsibility to family and community (Hau & Ho, 2010).

As in Finland, all students in Japan, Korea, and Taiwan receive the same nationally mandated, high-quality instruction, delivered by teachers who are well-prepared, highly respected in their society, and far better paid than U.S. teachers (Kang & Hong, 2008; U.S. Department of Education, 2015).

The Finnish and Asian examples underscore the need for American families, schools, and the larger society to work together to upgrade education. Recommended strategies, verified by research, include:

- supporting parents in attaining economic security, creating stimulating home learning environments, monitoring their children's academic progress, and communicating often with teachers
- investing in high-quality preschool education, so every child arrives at school ready to learn
- strengthening teacher education
- providing intellectually challenging, relevant instruction with real-world applications
- vigorously pursuing school improvements that reduce the large inequities in quality of education between SES and ethnic groups.

A Finnish teacher passes out materials to her second-grade students. Finland's teachers are highly trained, and their education system—designed to cultivate initiative, problem solving, and creativity in all students—has nearly eliminated SES variations in achievement.

## Ask yourself

**CONNECT** Review research on child-rearing styles on pages 282–283 in Chapter 8. What style do gifted children who realize their potential typically experience? Explain.

**APPLY** Sandy wonders why her daughter Mira's teacher often has students work on assignments in small, cooperative groups. Explain the benefits of this approach to Sandy.

**REFLECT** What grouping practices were used in your elementary education—homogeneous, heterogeneous, or a combination? What impact do you think those practices had on your motivation and achievement?

## Summary

### PHYSICAL DEVELOPMENT

#### Body Growth (p. 294)

##### 9.1 Describe major trends in body growth during middle childhood.

- During middle childhood, physical growth continues at a slow, regular pace. Bones lengthen and broaden, and permanent teeth replace the primary teeth. By age 9, girls overtake boys in physical size.

#### Common Health Problems (p. 295)

##### 9.2 Describe the causes and consequences of serious nutritional problems in middle childhood, giving special attention to obesity.

- Many poverty-stricken children suffer from serious and prolonged malnutrition, which can permanently impair physical and mental development.
- Overweight and **obesity** have increased dramatically in both industrialized and developing nations, with large gains in the United States. Although heredity contributes to obesity, parental feeding practices, maladaptive eating habits, reduced sleep, lack of exercise, and unhealthy diets are powerful influences. Obesity leads to serious physical health and adjustment problems.
- The most effective approaches to treating childhood obesity are family-based interventions aimed at changing parents' and children's eating patterns and lifestyles. Schools can help by serving healthier meals and ensuring regular physical activity.

ZACK WITTMAN FOR THE BOSTON GLOBE  
VIA GETTY IMAGES

##### 9.3 What vision and hearing problems are common in middle childhood?

- The most common vision problem, myopia, is influenced by heredity, early biological trauma, and time spent doing close work. It is one of the few health conditions that increases with SES.

- Although ear infections decline during the school years, many low-SES children experience some hearing loss because of repeated untreated middle-ear infections.

##### 9.4 What factors contribute to illness during the school years, and how can these health problems be reduced?

- Children experience more illnesses during the first two years of elementary school than later because of exposure to sick children and an immature immune system.
- The most common cause of school absence and childhood hospitalization is asthma. It occurs more often among African-American and poverty-stricken children, as well as obese children.
- Children with severe chronic illnesses are at risk for academic, emotional, and social difficulties, but positive family relationships improve adjustment.

##### 9.5 Describe changes in the occurrence of unintentional injuries in middle childhood, and cite effective interventions.

- Unintentional injuries increase from middle childhood into adolescence, especially for boys. Auto and bicycle accidents account for most of the rise.
- Effective school-based injury-prevention programs use modeling, rehearsal, and rewards for acquiring safety skills.

#### Motor Development and Play (p. 299)

##### 9.6 Cite major changes in motor development and play during middle childhood.

- Gains in flexibility, balance, agility, and force, along with more efficient information processing, contribute to school-age children's improved gross-motor performance.
- Fine-motor development also improves. Handwriting becomes more legible, and children's drawings increase in organization, detail, and representation of depth.
- Although girls outperform boys in fine-motor skills, boys outperform girls in all gross-motor skills except those requiring balance and agility. Parents' higher expectations for boys' athletic performance play a large role.

- Games with rules become common during the school years, contributing to emotional and social development. Children, especially boys, also engage in **rough-and-tumble play**—friendly play-fighting that helps establish a **dominance hierarchy** among group members.
- Most U.S. school-age children are not active enough for good health, in part because of cutbacks in recess and physical education.

### COGNITIVE DEVELOPMENT

#### Piaget's Theory: The Concrete Operational Stage (p. 304)

##### 9.7 What are the major characteristics of concrete operational thought?

- In the **concrete operational stage**, children's thought becomes more logical, flexible, and organized. Mastery of conservation demonstrates decentration and **reversibility** in thinking.
- School-age children are also better at hierarchical classification and **seriation**, including **transitive inference**. Their spatial reasoning improves, evident in their ability to create **cognitive maps** representing familiar large-scale spaces.
- Concrete operational thought is limited in that children do not come up with general logical principles. They master concrete operational tasks step by step.

##### 9.8 Discuss follow-up research on concrete operational thought.

- Specific cultural practices, especially those associated with schooling, promote children's mastery of Piagetian tasks.

© LAUREN GREENFIELD/INSTITUTE X

- Some researchers attribute the gradual development of operational thought to expansion of information-processing capacity. Case's neo-Piagetian theory proposes that with brain development and practice, cognitive schemes become more automatic, freeing up space in working memory for combining old schemes and generating new ones that are integrated into improved, broadly applicable representations.

## Information Processing (p. 307)

### 9.9 Describe gains in executive function and memory in middle childhood, along with factors that influence children's progress.

- As the prefrontal cortex continues to develop, children make great strides in executive function, enabling them to handle increasingly complex tasks that require integration of working memory, inhibition, and flexible shifting of attention. Planning on multistep tasks also improves.
- Heredity and environmental factors, including home and school experiences, combine to influence children's executive-function skills. Deficits in executive function underlie symptoms of **attention-deficit hyperactivity disorder (ADHD)**.
- Memory strategies also improve. **Rehearsal** appears first, followed by **organization** and then **elaboration**. With age, children combine memory strategies.

© KAREL NAVARRO/AP IMAGES

- Development of children's general knowledge base, or semantic memory, facilitates strategic memory processing, as does their motivation to use what they know. Societal modernization is broadly associated with cognitive performance, including on memory tasks.

### 9.10 Describe the school-age child's theory of mind and capacity to engage in self-regulation.

- School-age children regard the mind as an active, constructive agent, yielding a better understanding of cognitive processes, including effective memory strategies, mental inference, and second-order false belief, which requires **recursive thought**. **Cognitive self-regulation** develops gradually, improving with adult instruction in strategy use.

### 9.11 Discuss current perspectives on teaching reading and mathematics to elementary school children.

- Skilled reading draws on all aspects of the information-processing system. A combination of **whole language** and **phonics** is most effective for teaching beginning reading. Teaching that blends practice in basic skills with conceptual understanding also is best in mathematics.

## Individual Differences in Mental Development (p. 314)

### 9.12 Describe major approaches to defining and measuring intelligence.

- In middle childhood, IQ becomes more stable and correlates moderately with academic achievement. Most intelligence tests yield an overall score as well as scores for separate intellectual factors. Processing speed and executive function predict IQ.
- Sternberg's **triarchic theory of successful intelligence** identifies three broad, interacting intelligences: analytical intelligence (information-processing skills), creative intelligence (capacity to solve novel problems), and practical intelligence (application of intellectual skills in everyday situations).
- Gardner's **theory of multiple intelligences** identifies at least eight distinct mental abilities. It has stimulated efforts to define, measure, and foster emotional intelligence.

### 9.13 Describe evidence indicating that both heredity and environment contribute to intelligence.

- Heritability estimates and adoption research indicate that intelligence is a product of both heredity and environment. Adoption studies suggest that environmental factors underlie the black–white IQ gap. The **Flynn effect**, steady generational changes in IQ in many nations, is closely associated with extent of societal modernization.
- IQ scores are affected by culturally influenced language communication styles, knowledge, and amount of time spent in school. **Stereotype threat** triggers anxiety that interferes with test performance. **Dynamic assessment** helps many minority children perform more competently on mental tests.

## Language Development (p. 322)

### 9.14 Describe changes in school-age children's vocabulary, grammar, and pragmatics, and cite the advantages of bilingualism for development.

- Language awareness contributes to language progress. School-age children have a more precise and flexible understanding of word meanings and use more complex grammatical constructions and conversational strategies. Narratives increase in organization, detail, and expressiveness.

- Mastery of a second language must begin in childhood for full proficiency to occur. Bilingualism has positive consequences for executive function, various other cognitive skills, and aspects of language awareness.

© CHRISTINA KENNEDY/PHOTODEBIT

## Learning in School (p. 324)

### 9.15 Describe the influence of educational philosophies on children's motivation and academic achievement.

- Older students in **traditional classrooms** have a slight edge in achievement test scores over those in **constructivist classrooms**, who gain in critical thinking, social and moral maturity, and positive attitudes toward school.
- Students in **social-constructivist classrooms** benefit from working collaboratively in meaningful activities and from teaching adapted to each child's zone of proximal development. Children benefit from teacher support for **cooperative learning** with peers, which promotes complex reasoning and achievement gains.

### 9.16 Discuss the role of teacher–student interaction and grouping practices in academic achievement.

- Caring, helpful, and stimulating teaching fosters children's motivation, achievement, and peer relations. **Educational self-fulfilling prophecies** have a greater impact on low than high achievers and are especially likely to occur in classrooms that emphasize competition and public evaluation. Homogeneous grouping can induce self-fulfilling prophecies in low-group students, who decline in self-esteem and achievement.

© OLIVER MORIN/AP/GETTY IMAGES

**9.17** *Under what conditions is placement of children with learning difficulties in regular classrooms successful?*

- The success of **inclusive classrooms** for students with mild intellectual disability and **learning disabilities** depends on meeting individual learning needs and promoting positive peer relations.

**9.18** *Describe the characteristics of gifted children and current efforts to meet their educational needs.*

- **Giftedness** includes high IQ, **creativity**, and **talent**. Tests of creativity that tap **divergent thinking** rather than **convergent thinking** focus on only one of the ingredients of creativity. Highly talented children generally have parents and teachers who nurture their exceptional abilities.

**9.19** *How well-educated are U.S. children compared with children in other industrialized nations?*

- In international studies, U.S. students typically perform at or below international averages. Compared with education in top-achieving nations, education in the United States is less focused on high-level reasoning and critical thinking, and less equitable across SES groups.

## Emotional and Social Development in Middle Childhood

Having fled their war-torn homeland of Syria, school-age friends nestle together in a barren refugee camp in Jordan. In middle childhood, trust—mutual kindness and assistance—becomes a defining feature of friendship. For children experiencing the dislocation and losses of war, friends can serve as a source of resilience.

### **SOCIAL ISSUES: HEALTH** Children's Eyewitness Testimony

One afternoon as school dismissed, Joey urgently tapped his best friend Terry on the shoulder. “Gotta talk to you,” Joey pleaded. “Everything was going great until I got that word—*porcupine*,” Joey went on, referring to the fifth-grade spelling bee that day. “Just my luck! *P-o-r-k*, that’s how I spelled it! I can’t believe it. I *know* I’m one of the best spellers in our class, better than that stuck-up Belinda Brown. I knocked myself out studying those spelling lists. Then *she* got all the easy words. If I *had* to lose, why couldn’t it be to a nice person?”

Joey’s conversation reflects new emotional and social capacities. By entering the spelling bee, he shows *industriousness*, the energetic pursuit of meaningful achievement in his culture—a major change of middle childhood. Joey’s social understanding has also expanded: He can size up strengths, weaknesses, and personality characteristics. Furthermore, friendship means something different to Joey than it did earlier: He counts on his best friend, Terry, for understanding and emotional support.

For an overview of the personality changes of middle childhood, we return to Erikson’s theory. Then we look at children’s views of themselves and of others, their moral understanding, and their peer relationships. Each increases in complexity as children reason more effectively and spend more time in school and with agemates.

Despite changing parent–child relationships, the family remains powerfully influential in middle childhood. Today, family structures are more diverse than ever before. Through Joey and his younger sister Lizzie’s experiences with parental divorce, we will see that family functioning is far more important than family structure in ensuring children’s well-being. Finally, we look at some common emotional problems of middle childhood. ●

## Erikson's Theory: Industry versus Inferiority

**10.1** What personality changes take place during Erikson's stage of industry versus inferiority?

According to Erikson (1950), children whose previous experiences have been positive enter middle childhood prepared to focus their energies on realistic accomplishment. Erikson believed that the combination of adult expectations and children's drive toward mastery sets the stage for the psychological conflict of middle childhood, **industry versus inferiority**, which is resolved positively when experiences lead children to develop a sense of competence at useful skills and tasks. In cultures everywhere, adults respond to children's improved physical and cognitive capacities by making new demands, and children are ready to benefit from those challenges.

In most of the world, the transition to middle childhood is marked by the beginning of formal schooling, where children discover their own and others' unique capacities, learn the value of division of labor, and develop a sense of moral commitment and responsibility. The danger at this stage is *inferiority*, reflected in the pessimism of children who lack confidence in their ability to do things well. This sense of inadequacy can develop when family life has not prepared children for school life or when teachers and peers destroy children's self-confidence with negative responses.

Erikson's sense of industry combines several developments of middle childhood: a positive but realistic self-concept, pride in accomplishment, moral responsibility, and cooperative participation with age-mates. How do these aspects of self and social relationships change over the school years?

ECO IMAGES/GETTY IMAGES

The industriousness of middle childhood involves responding to new expectations for realistic accomplishment. In the informal, encouraging atmosphere of this classroom in India, children come to view themselves as responsible, capable, and cooperative.

## Self-Understanding

**10.2** Describe school-age children's self-concept and self-esteem, and discuss factors that affect their achievement-related attributions.

In middle childhood, children begin to describe themselves in terms of psychological traits, compare their own characteristics with those of their peers, and speculate about the causes of their strengths and weaknesses. These transformations in self-understanding have a major impact on self-esteem.

### Self-Concept

During the school years, children refine their self-concept, organizing their observations of behaviors and internal states into general dispositions. A major change takes place between ages 8 and 11, as the following self-description by a fourth grader illustrates:

I'm pretty popular, at least with the girls who I spend time with, but not with the super-popular girls who think they are cooler than everyone else. With my friends, I know what it takes to be liked, so I'm nice to people and helpful and can keep secrets. . . . Sometimes, if I get in a bad mood I'll say something that can be a little mean and then I'm ashamed of myself. At school, I'm feeling pretty smart in certain subjects like language arts and social studies, someday I will probably get a job that depends on having good English skills. . . . But I'm feeling pretty dumb in math and science, especially when I see how well a lot of the other kids are doing. I now understand that I can be both smart and dumb, you aren't just one or the other. (Harter, 2012, p. 59).

Instead of specific behaviors, this child emphasizes competencies: "smart in certain subjects like language arts and social studies" and "having good English skills." She also describes her personality, mentioning both positive and negative traits: "helpful" and "can keep secrets" but sometimes "a little mean." Older school-age children are far less likely than younger children to describe themselves in extreme, all-or-none ways (Harter, 2012a).

These evaluative self-descriptions result from school-age children's frequent **social comparisons**—judgments of their appearance, abilities, and behavior in relation to those of others. Notice, in the introduction to this chapter, Joey's observation that he is "one of the best spellers" in his class. Similarly, our fourth grader's self-description mentions feeling "smart" at some subjects but not at others, especially when she sees "how well a lot of the other kids are doing." Whereas 4- to 6-year-olds can compare their own performance to that of a single peer, older children can compare multiple individuals, including themselves (Harter, 2012).

What factors account for these revisions in self-concept? Cognitive development affects the changing *structure* of the self. School-age children can better coordinate several aspects of a situation in reasoning about their physical world. Similarly, in the social realm, they combine typical experiences and behaviors

into stable psychological dispositions, blend positive and negative characteristics, and compare their own characteristics with those of many peers.

The changing *content* of self-concept is a product of both cognitive capacities and feedback from others. Sociologist George Herbert Mead (1934) proposed that a well-organized psychological self emerges when children adopt a view of the self that resembles others' attitudes toward the child. Mead's ideas indicate that *perspective-taking skills*—in particular, an improved ability to infer what other people are thinking and to distinguish those viewpoints from one's own—are crucial for developing a self-concept based on personality traits. In Chapter 9, we saw that middle childhood brings the capacity for recursive thought, which enables school-age children to “read” others' messages more accurately and internalize their expectations. As they do so, they form an *ideal self* that they use to evaluate their real self. A large discrepancy between the two, as we will soon see, can undermine self-esteem.

Parental support for self-development continues to be vitally important. School-age children with a history of elaborative parent-child conversations about past experiences construct rich, positive narratives about the self and therefore have more complex, favorable, and coherent self-concepts (Baddeley & Singer, 2015). Children also look to more people beyond the family for information about themselves as they enter a wider range of settings in school and community. And self-descriptions now include frequent reference to social groups: “I'm a Boy Scout, a paper boy, and a Prairie City soccer player,” said Joey. As children move into adolescence, although parents and other adults remain influential, self-concept is increasingly vested in feedback from close friends (Oosterwegel & Oppenheimer, 1993).

But recall that the content of self-concept varies from culture to culture. In earlier chapters, we noted that Asian parents stress harmonious interdependence, whereas Western parents emphasize independence and self-assertion. When asked to recall personally significant past experiences (their last birthday, a time their parent scolded them), U.S. school-age children gave longer accounts including more personal preferences, interests, skills, and opinions. Chinese children, in contrast, more often referred to social interactions and to others. Similarly, in their self-descriptions, U.S. children listed more personal attributes (“I'm smart,” “I like hockey”), Chinese children more attributes involving group membership and relationships (“I'm in second grade,” “My friends are crazy about me”) (Wang, 2006; Wang, Shao, & Li, 2010).

## Self-Esteem

Recall that most preschoolers have extremely high self-esteem. But as children enter school and receive much more feedback about how well they perform compared with their peers, self-esteem differentiates and also adjusts to a more realistic level.

To study school-age children's self-esteem, researchers ask them to indicate the extent to which statements such as “I'm good at reading” or “I'm usually the one chosen for games” are true of themselves. By age 6 to 7, children in diverse Western

cultures have formed at least four broad self-evaluations: academic competence, social competence, physical/athletic competence, and physical appearance. Within these are more refined categories that become increasingly distinct with age (Marsh, 1990; Marsh & Ayotte, 2003; Van den Bergh & De Rycke, 2003). Furthermore, the capacity to view the self in terms of stable dispositions permits school-age children to combine their separate self-evaluations into a general psychological image of themselves—an overall sense of self-esteem (Harter, 2012). As a result, self-esteem takes on the hierarchical structure shown in Figure 10.1 on page 338.

Children attach greater importance to certain self-evaluations than to others. Although individual differences exist, during childhood and adolescence, perceived physical appearance correlates more strongly with overall self-worth than does any other self-esteem factor (O'Dea, 2012; Shapka & Keating, 2005). Emphasis on appearance—in the media, by parents and peers, and in society—has major implications for young people's overall satisfaction with themselves.

Self-esteem generally remains high during elementary school but becomes more realistic and nuanced as children evaluate themselves in various areas (Marsh, Craven, & Debus, 1998; Wigfield et al., 1997). These changes occur as children receive more competence-related feedback, as their performances are increasingly judged in relation to those of others, and as they become cognitively capable of social comparison (Harter, 2012a).

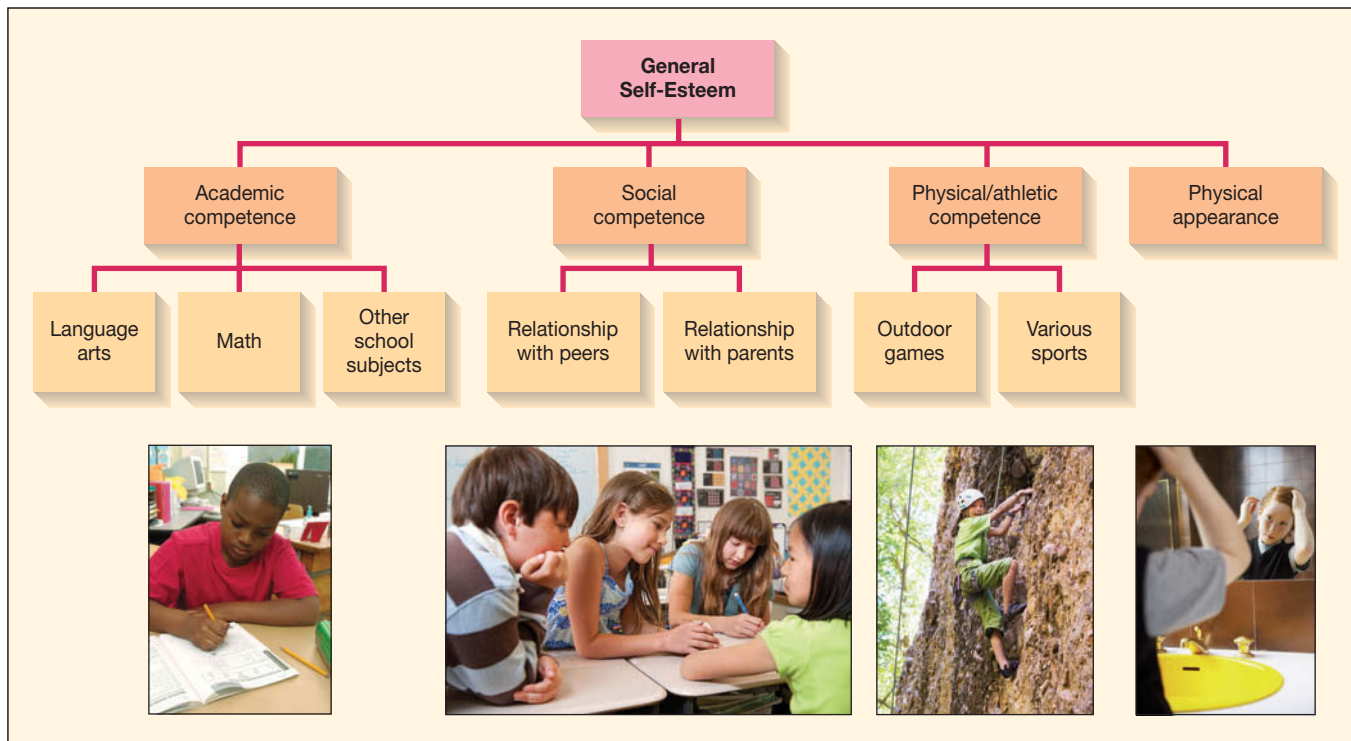

## Influences on Self-Esteem

From middle childhood on, individual differences in self-esteem become increasingly stable (Trzesniewski, Donnellan, & Robins, 2003). And positive relationships among self-esteem, valuing of various activities, and success at those activities emerge and strengthen. Academic self-esteem predicts how important, useful, and enjoyable children judge school subjects to be, willingness to try hard, achievement, and eventual career choice (Denissen, Zarrett, & Eccles, 2007; Valentine, DuBois, & Cooper, 2004; Whitesell et al., 2009). Children with high social self-esteem are consistently better-liked by classmates (Jacobs et al., 2002). And as Chapter 9 revealed, sense of athletic competence is positively associated with investment in and performance at sports.

A profile of low self-esteem in all areas is linked to anxiety, depression, and increasing antisocial behavior (Kim & Cicchetti, 2006; Robins et al., 2001; Sowislo & Orth, 2013). What social influences might lead self-esteem to be high for some children and low for others?

**Culture, Gender, and Ethnicity.** Cultural forces profoundly affect self-esteem. An especially strong emphasis on social comparison in school may explain why Chinese and Japanese children, despite their higher academic achievement, score lower than U.S. children in self-esteem—a difference that widens with age (Harter, 2012; Twenge & Crocker, 2002). At the same time, because their cultures value social harmony, Asian children tend to be reserved in positive self-judgments but generous in praise of others (Falbo et al., 1997).

**FIGURE 10.1** Hierarchical structure of self-esteem in the mid-elementary school years. From their experiences in different settings, children form at least four separate self-esteems: academic competence, social competence, physical/athletic competence, and physical appearance. These differentiate into additional self-evaluations and combine to form a general sense of self-esteem.

Gender-stereotyped expectations also affect self-esteem. In one study, the more 5- to 8-year-old girls talked with friends about the way people look, watched TV shows focusing on physical appearance, and perceived their friends as valuing thinness, the greater their dissatisfaction with their physical self and the lower their overall self-esteem a year later (Dohnt & Tiggemann,

2006). In another investigation, being overweight was more strongly linked to negative body image for third-grade girls than for boys (Shriver et al., 2013). By the end of middle childhood, girls feel less confident than boys about their physical appearance and athletic abilities. With respect to academic self-esteem, boys, again, are somewhat advantaged: Whereas girls score higher in language arts self-esteem, boys have higher math and science self-esteem—even when children of equal skill levels are compared (Jacobs et al., 2002; Kurtz-Costes et al., 2008). At the same time, girls exceed boys in self-esteem dimensions of close friendship and social acceptance.

Compared with their European-American agemates, African-American children tend to have slightly higher self-esteem, possibly because of warm extended families and a stronger sense of ethnic pride (Gray-Little & Hafdahl, 2000). Consistent with this interpretation, African-American 7- to 10-year-olds randomly assigned to a 10-session, small-group program celebrating black family life and culture gained in self-esteem relative to agemates assigned to a no-intervention control (Okeke-Adeyanju et al., 2014). Finally, children and adolescents who attend schools or live in neighborhoods where their SES and ethnic groups are well-represented feel a stronger sense of belonging and have fewer self-esteem problems (Gray-Little & Carels, 1997).

**Child-Rearing Practices.** School-age children with a strong sense of attachment security and whose parents use an *authoritative* child-rearing style (see Chapter 8) feel especially good about themselves (Kerns, Brumariu, & Seibert, 2011;

AP IMAGES/THE DAY, SEAN D. ELLIOT

Children learn African drumming skills at a community center during Kwanzaa, a holiday honoring their African heritage. A stronger sense of ethnic pride may contribute to slightly higher self-esteem among African-American children compared with their European-American agemates.

Yeung et al., 2016). Warm, positive parenting lets children know that they are accepted as competent and worthwhile. And firm but appropriate expectations, backed up with explanations, help them evaluate their own behavior against reasonable standards.

Controlling parents—those who too often help or make decisions for their child, often because their own sense of self-worth hinges on their child’s performance—communicate a sense of inadequacy to children. Having parents who are repeatedly disapproving and insulting is also linked to low self-esteem (Kernis, 2002; Wuyts et al., 2015). Children subjected to such parenting need constant reassurance, and many rely heavily on peers to affirm their self-worth—a risk factor for adjustment difficulties, including aggression and antisocial behavior (Donnellan et al., 2005). In contrast, indulgent parenting is associated with unrealistically high self-esteem. These children are vulnerable to temporary, sharp drops in self-esteem when their overblown self-images are challenged (Thomaes et al., 2013). They tend to lash out at peers who express disapproval and to display adjustment problems, including meanness and aggression (Hughes, Cavell, & Grossman, 1997; Thomaes et al., 2008).

American cultural values have increasingly emphasized a focus on the self that may lead parents to indulge children and boost their self-esteem too much. The self-esteem of U.S. youths has risen sharply in recent decades—a period in which much popular parenting literature, educational policies, and social programs have advised promoting children’s self-esteem (Gentile, Twenge, & Campbell, 2010). Research, however, confirms that children do not benefit from compliments (“You’re terrific”) that have no basis in real accomplishment (Wentzel & Brophy, 2014). Rather, the best way to foster a positive, secure self-image is to encourage children to strive for worthwhile goals. Over time, a bidirectional relationship emerges: Achievement fosters self-esteem, which contributes to further effort and gains in performance (Marsh et al., 2005).

What can adults do to promote, and to avoid undermining, this mutually supportive relationship between motivation and self-esteem? Some answers come from research on the precise content of adults’ messages to children in achievement situations.

**Achievement-Related Attributions.** *Attributions* are our common, everyday explanations for the causes of behavior. Notice how Joey, in talking about the spelling bee at the beginning of this chapter, attributes his disappointing performance to *luck* (Belinda got all the easy words) and his usual success to *ability* (he *knows* he’s a better speller than Belinda). Joey also appreciates that *effort* matters: “I knocked myself out studying those spelling lists.”

The combination of improved reasoning skills and frequent evaluative feedback permits 10- to 12-year-olds to separate all these variables in explaining performance. Those who are high in academic self-esteem and motivation make **mastery-oriented attributions**, crediting their successes to ability—a characteristic they can improve through trying hard and can count on when faced with new challenges. And they attribute failure to factors

that can be changed or controlled, such as insufficient effort or a difficult task (Dweck & Molden, 2013). Whether these children succeed or fail, they take an industrious, persistent approach to learning.

In contrast, children who develop **learned helplessness** attribute their failures, not their successes, to ability. When they succeed, they conclude that external factors, such as luck, are responsible. Unlike their mastery-oriented counterparts, they believe that ability is fixed and cannot be improved by trying hard (Dweck & Molden, 2013). When a task is difficult, these children experience an anxious loss of control—in Erikson’s terms, a pervasive sense of inferiority. They give up without really trying.

Children’s attributions affect their goals. Mastery-oriented children seek information on how best to increase their ability through effort. Hence, their performance improves over time (Dweck & Molden, 2013). In contrast, learned-helpless children focus on obtaining positive and avoiding negative evaluations of their fragile sense of ability. Gradually, their ability ceases to predict how well they do. In one study, the more fourth to sixth graders held self-critical attributions, the lower they rated their competence, the less they knew about effective study strategies, the more they avoided challenge, and the poorer their academic performance (Pomerantz & Saxon, 2001). Because learned-helpless children fail to connect effort with success, they do not develop the metacognitive and self-regulatory skills necessary for high achievement (see Chapter 9). Lack of effective learning strategies, reduced persistence, and a sense of loss of control sustain one another in a vicious cycle.

### Influences on Achievement-Related Attributions.

What accounts for the different attributions of mastery-oriented and learned-helpless children? Adult communication plays a key role (Pomerantz & Dong, 2006.) Children with a learned-helpless style often have parents who believe that their child is not very capable and must work harder than others to succeed. When the child fails, the parent might say, “You can’t do that, can you? It’s OK if you quit” (Hokoda & Fincham, 1995). Similarly, students with unsupportive teachers often regard their performance as externally controlled (by their teachers or by luck), withdraw from learning activities, decline in achievement, and come to doubt their ability (Skinner, Zimmer-Gembeck, & Connell, 1998).

When a child succeeds, adults can offer **person praise**, which emphasizes the child’s traits (“You’re so smart!”), or **process praise**, which emphasizes behavior and effort (“You figured it out!”). Children—especially those with low self-esteem—feel more shame following failure if they previously received person praise, less shame if they previously received process praise or no praise at all (Brummelman et al., 2014). Consistent with a learned-helpless orientation, person praise teaches children that abilities are fixed, which leads them to question their competence and retreat from challenges (Pomerantz & Kempner, 2013). In contrast, process praise—consistent with a mastery orientation—implies that competence develops through effort (Pomerantz, Grolnick, & Price, 2013).

For some children, performance is especially likely to be undermined by adult feedback. Despite their higher achievement, girls more often than boys attribute poor performance to lack of ability. When girls do not do well, they tend to receive messages from teachers and parents that their ability is at fault, and negative stereotypes (for example, that girls are weak at math) undermine their interest and effort (Gunderson et al., 2012; Tomasetto, Alparone, & Cadinu, 2011). And as Chapter 9 revealed, low-SES ethnic minority students often receive less favorable feedback from teachers, especially when assigned to homogeneous groups of poorly achieving students—conditions that result in a drop in academic self-esteem and achievement.

### LOOK and LISTEN

Observe a school-age child working on a challenging homework assignment under the guidance of a parent or other adult. What features of the adult's communication likely foster mastery-oriented attributions? How about learned helplessness? Explain.

Finally, cultural values influence children's views about success and failure. Asian parents and teachers are more likely than their American counterparts to view effort as key to success. Asian children, in turn, feel a stronger sense of obligation toward parents, internalizing their messages (Mok, Kennedy, & Moore, 2011; Qu & Pomerantz, 2015). Asians also attend more to failure than to success because failure indicates where corrective action is needed. Americans, in contrast, focus more on success because it enhances self-esteem. Observations of U.S. and Chinese mothers' responses to their fourth and fifth graders' puzzle solutions revealed that the U.S. mothers offered more

© HERO IMAGES/CORBIS

When adults offer process praise emphasizing behavior and effort, children learn that persistence builds competence. Teacher remarks, such as “You found a good way to solve that problem!” will foster a mastery-oriented approach in this student.

**FIGURE 10.2** Chinese and U.S. mothers' task-relevant statements in response to their fourth-grade child's success or failure on puzzle tasks. Observations revealed that regardless of whether their child had just succeeded or failed, Chinese mothers were more likely than U.S. mothers to make task-relevant statements aimed at ensuring that the child exerted high effort. (Based on Ng, Pomerantz, & Lam, 2007.)

praise after success, whereas the Chinese mothers more often pointed out the child's inadequate performance. And Chinese mothers made more task-relevant statements aimed at ensuring that children exerted sufficient effort (“You concentrated on it”; “You only got 6 out of 12”) (see Figure 10.2) (Ng, Pomerantz, & Lam, 2007). When children continued with the task after mothers left the room, the Chinese children showed greater gains in performance.

**Fostering a Mastery-Oriented Approach.** An intervention called *attribution retraining* encourages learned-helpless children to believe that they can overcome failure by exerting more effort and using more effective strategies. Children are given tasks difficult enough that they will experience some failure, followed by repeated feedback that helps them revise their attributions: “You can do it if you try harder.” After they succeed, children are given process praise—“Your strategies worked”; “You really tried hard on that one”—so that they attribute their success to both effort and effective strategies, not chance. Another approach is to encourage low-effort students to focus on mastering a task for its own sake, not on grades, and on individual improvement, not on comparisons with classmates (Wentzel & Brophy, 2014). Instruction in effective strategies and self-regulation is also vital, to compensate for development lost in this area and to ensure that renewed effort pays off (Berkeley, Mastropieri, & Scruggs, 2011).

Attribution retraining is best begun early, before children's views of themselves become hard to change. An even better approach is to prevent learned helplessness, using the strategies summarized in Applying What We Know on the following page.

## Applying what we Know

### Fostering a Mastery-Oriented Approach to Learning

STRATEGY	DESCRIPTION
Provision of tasks	Select tasks that are meaningful, responsive to a diversity of student interests, and appropriately matched to current competence so that the child is challenged but not overwhelmed.
Parent and teacher encouragement	Communicate warmth, confidence in the child's abilities, the value of achievement, and the importance of effort in success. Resist praising children's personal qualities, focusing instead on their competent behavior, sustained effort, and successful strategies. Model high effort in overcoming failure. <i>For teachers:</i> Communicate often with parents, suggesting ways to foster children's effort and progress. <i>For parents:</i> Monitor schoolwork; provide scaffolded assistance that promotes knowledge of effective strategies and self-regulation.
Performance evaluations	Make evaluations private; avoid publicizing success or failure through wall posters, stars, privileges for "smart" children, or prizes for "best" performance. Emphasize individual progress and self-improvement. Provide accurate, constructive feedback to children about their performance.
School environment	Provide for cooperative learning and peer tutoring, in which children assist one another; avoid ability grouping, which makes evaluations of children's progress public. Accommodate individual and cultural differences in learning styles. Create an atmosphere that sends a clear message that all students can learn.

## Ask yourself

**CONNECT** What cognitive changes, described in Chapter 9, support the transition to a self-concept emphasizing competencies, personality traits, and social comparisons?

**APPLY** Should parents try to promote children's self-esteem by telling them they're "smart" or "wonderful"? Are children harmed if they do not feel good about everything they do? Explain.

**REFLECT** Recall your own attributions for academic successes and failures when you were in elementary school. What are those attributions like now? What messages from others may have contributed to your attributions?

## Emotional Development

**10.3** Cite changes in self-conscious emotions, emotional understanding, and emotional self-regulation in middle childhood.

Greater self-awareness and social sensitivity support advances in emotional competence in middle childhood. Gains take place in experience of self-conscious emotions, emotional understanding, and emotional self-regulation.

## Self-Conscious Emotions

As school-age children integrate social expectations into their self-concepts, self-conscious emotions of pride and guilt become clearly governed by personal responsibility. Children experience pride in a new accomplishment and guilt over a transgression, even when no adult is present (Harter, 2012). Also, children no longer report guilt for any mishap, as they did earlier, but only for intentional wrongdoing, such as ignoring responsibilities, cheating, or lying (Ferguson, Stegge, & Damhuis, 1991). These changes reflect the older child's more mature sense of morality, a topic addressed later in this chapter.

Pride motivates children to take on further challenges, whereas guilt prompts them to make amends and to strive for self-improvement. But in Chapter 8 we noted that excessive guilt is linked to depressive symptoms. And harsh, insensitive reprimands from adults ("Everyone else can do it! Why can't you?") can lead to intense shame, which is particularly destructive, yielding both internalizing and externalizing problems (see page 262).

## Emotional Understanding

School-age children's understanding of mental activity means that, unlike preschoolers, they are likely to explain emotion by referring to internal states, such as happy or sad thoughts, rather than to external events (Flavell, Flavell, & Green, 2001). Also, between ages 6 and 12, children become more aware of circumstances

AP IMAGES/THE EVANSVILLE COURIER &amp; PRESS, JASON CLARK

Third graders help prepare meal packages to be sent to Africa to feed children in need. Gains in emotional understanding and perspective taking enable children to respond with empathy to people's general life condition.

likely to spark mixed emotions, each of which may be positive or negative and may differ in intensity (Pons et al., 2003; Zadjel et al., 2013). For example, recalling the birthday present he received from his grandmother, Joey reflected, “I was very happy that I got something but a little sad that I didn’t get just what I wanted.”

Appreciating mixed emotions helps children realize that people’s expressions may not reflect their true feelings (Misailidi, 2006). It also fosters awareness of self-conscious emotions. For example, between ages 6 and 7, children improve sharply in ability to distinguish pride from happiness and surprise (Tracy, Robins, & Lagattuta, 2005). And 8- and 9-year-olds understand that pride combines two sources of happiness—joy in accomplishment and joy that a significant person recognized that accomplishment (Harter, 1999). Furthermore, children of this age can reconcile contradictory facial and situational cues in figuring out another’s feelings (see page 261 in Chapter 8).

As with self-understanding, gains in emotional understanding are supported by cognitive development and social experiences, especially adults’ sensitivity to children’s feelings and willingness to discuss emotions. Together, these factors lead to a rise in empathy as well. As children move closer to adolescence, advances in recursive perspective taking permit an empathic response not just to people’s immediate distress but also to their general life condition (Hoffman, 2000). As Joey and Lizzie imagined how people who are chronically ill or hungry feel and evoked those emotions in themselves, they gave part of their allowance to charity and joined in fundraising projects through school, community center, and scouting.

## Emotional Self-Regulation

In Chapter 8, we saw that emotional understanding, along with parents’ modeling and teaching of emotion-regulation strategies, contributes to young children’s ability to manage emotions. These factors continue to play important roles during middle

childhood, a period of rapid gains in emotional self-regulation (Zalewski et al., 2011).

By age 10, most children shift adaptively between two general strategies for managing emotion. In **problem-centered coping**, they appraise the situation as changeable, identify the difficulty, and decide what to do about it. If problem solving does not work, they engage in **emotion-centered coping**, which is internal, private, and aimed at controlling distress when little can be done about an outcome (Kliewer, Fearnow, & Miller, 1996; Lazarus & Lazarus, 1994). For example, when faced with an anxiety-provoking test or an angry friend, older school-age children view problem solving and seeking social support as the best strategies. But when outcomes are beyond their control—after receiving a bad grade—they opt for distraction or try to redefine the situation: “Things could be worse. There’ll be another test.” School-age children’s improved ability to appraise situations and reflect on thoughts and feelings means that, compared with preschoolers, they more often use these internal strategies to manage emotion (Brenner & Salovey, 1997).

Furthermore, through interacting with parents, teachers, and peers, school-age children become more knowledgeable about socially approved ways to display negative emotion. They increasingly prefer verbal expression (“Please stop pushing and wait your turn”) to crying, sulking, or aggression (Waters & Thompson, 2014). Young school-age children justify these more mature displays of emotion by mentioning avoidance of punishment or adult approval, but by third grade, they begin to emphasize concern for others’ feelings. Children with this awareness are rated as especially helpful, cooperative, and socially responsive by teachers and as better-liked by peers (Garner, 1996; McDowell & Parke, 2000).

When emotional self-regulation has developed well, school-age children acquire a sense of *emotional self-efficacy*—a feeling of being in control of their emotional experience (Thompson & Goodman, 2010). This fosters a favorable self-image and an optimistic outlook, which further help children face emotional challenges. As at younger ages, school-age children whose parents respond sensitively and helpfully when the child is distressed are emotionally well-regulated—generally upbeat in mood and also empathic and prosocial. In contrast, poorly regulated children often experience hostile, dismissive parental reactions to distress (Morris et al., 2007; Vinik, Almas, & Grusec, 2011). These children are overwhelmed by negative emotion, a response that interferes with empathy and prosocial behavior.

## Moral Development

**10.4** Describe changes in moral understanding during middle childhood, including children’s understanding of diversity and inequality.

Recall from Chapter 8 that preschoolers pick up many morally relevant behaviors through modeling and reinforcement. By middle childhood, they have had time to internalize rules for good conduct: “It’s good to help others in trouble” or “It’s wrong to take

something that doesn't belong to you." This change leads children to become considerably more independent and trustworthy.

In Chapter 8, we also saw that children do not just copy their morality from others. As the cognitive-developmental approach emphasizes, they actively think about right and wrong. An expanding social world, the capacity to consider more information when reasoning, and gains in recursive perspective taking lead moral understanding to advance greatly in middle childhood.

## Moral and Social-Conventional Understanding

During middle childhood, children construct a flexible appreciation of moral rules. They take into account an increasing number of variables—not just the action and its immediate impact, but also the actor's intentions and the context of his behavior (Killen & Smetana, 2015). For example, between ages 7 and 11, children say it is acceptable to hit another child in certain situations—in self-defense, to protect someone else from serious bodily injury, or to prevent the other child from hurting herself (Jambon & Smetana, 2014). Older children focus less on the actor's transgression (hitting) and more on the aim of his behavior (trying to prevent harm).

Similarly, by age 7 to 8, children no longer say that truth telling is always good and lying is always bad but consider prosocial and antisocial intentions and the context of the behavior. They evaluate certain types of truthfulness very negatively—for example, blunt statements, particularly in public contexts where they are especially likely to have negative social consequences (telling a classmate that you don't like her drawing) (Ma et al., 2011).

Although both Chinese and Canadian schoolchildren consider lying about antisocial acts “very naughty,” Chinese children more often rate lying favorably when the intention is modesty, as when a student who has thoughtfully picked up litter from the playground says, “I didn't do it” (Cameron et al., 2012; Lee et al., 2001). Similarly, Chinese children are more likely to favor lying to support the group at the expense of the individual (saying you're sick so, as a poor singer, you won't harm your class's chances of winning a singing competition). In contrast, Canadian children more often favor lying to support the individual at the expense of the group (claiming that a friend who is a poor speller is actually a good speller because the friend wants to participate in a spelling competition) (Fu et al., 2007; Lau et al., 2012).

These judgments reflect school-age children's enhanced understanding of varied reasons for deception (Mills, 2013). They realize that people may convey inaccurate information because they are biased, trying to be persuasive, concerned about how others may react, or protecting others' welfare. Notice how such perspective taking is *recursive*: Children must consider simultaneously the viewpoints of two or more people—the person who lies and the recipients of the lie.

Appreciation of second-order false belief, which depends on recursive thought (see page 312 in Chapter 9), is related to gains in moral judgment in middle childhood. In one study, researchers gave children a morally relevant second-order false-belief task:

A child, while helping her teacher clean up, accidentally throws out a bag containing a treasured cupcake belonging to a classmate who is out of the room (Fu et al., 2014). School-age children who reasoned accurately about the helper's belief about the bag's contents (trash) and the cupcake owner's belief about the cupcake's location (in a bag in the classroom) assigned less blame to the helper. Using their recursive capacity, these children inferred that *the cupcake owner would understand that the helper thought the bag had trash in it*.

As children construct more advanced ideas about justice, they clarify and link moral imperatives and social conventions. School-age children distinguish social conventions with a clear *purpose* (not running in school hallways to prevent injuries) from ones with no obvious justification (crossing a “forbidden” line on the playground) (Buchanan-Barrow & Barrett, 1998). They regard violations of purposeful social conventions as closer to moral transgressions.

## Understanding Individual Rights

When children challenge adult authority, they typically do so within the personal domain (Nucci, 2005). As their grasp of moral imperatives and social conventions strengthens, so does their conviction that certain choices, such as hairstyle, friends, and leisure activities, are up to the individual.

Notions of personal choice, in turn, enhance children's moral understanding. As early as age 6, children view freedom of speech and religion as individual rights, even if laws exist that deny those rights (Helwig, 2006). And they regard laws that discriminate against individuals—for example, denying certain people access to medical care or education—as wrong and worthy of violating (Helwig & Jasiobedzka, 2001). In justifying their responses, children appeal to personal privileges and, by the end of middle childhood, to the importance of individual rights for maintaining a fair society.

At the same time, older school-age children place limits on individual choice. Fourth graders faced with conflicting moral

New York City schoolchildren participate in the People's Climate March, which advocates for global action to prevent climate change. By age 6, children's more sophisticated grasp of personal choice enhances moral understanding, including freedom of speech.

and personal concerns—such as whether or not to befriend a classmate of a different race or gender—typically decide in favor of kindness and fairness (Killen et al., 2002). Indeed, high-quality friendships may play an important role in facilitating children’s moral sensibilities (McDonald et al., 2014). The cooperativeness, responsiveness, and empathic understanding between good friends promotes concern for others’ rights and welfare, while also highlighting the circumstances in which some transgressions ought to be forgiven.

## Culture and Moral Understanding

Children and adolescents in diverse cultures use similar criteria to reason about moral, social-conventional, and personal concerns (Nucci, 2005, 2008). For example, Chinese young people, whose culture places a high value on respect for adult authority, nevertheless say that adults have no right to interfere in children’s personal matters, such as how they spend free time (Hasebe, Nucci, & Nucci, 2004). A Colombian child illustrated this passionate defense of personal control when asked if a teacher had the right to tell a student where to sit during circle time. In the absence of a moral reason from the teacher, the child declared, “She should be able to sit wherever she wants” (Ardila-Rey & Killen, 2001, p. 249).

Furthermore, when a directive is fair and caring, such as telling children to share candy or to return lost money to its owner, school-age children view it as right, regardless of who states it—even a child with no authority. And even in Korean culture, which promotes children’s deference to adults, 7- to 11-year-olds evaluate negatively a teacher’s or principal’s order to engage in immoral acts, such as stealing or refusing to share (Kim, 1998). In sum, children everywhere seem to realize that higher principles, independent of rule and authority, must prevail when people’s personal rights and welfare are at stake.

## Understanding Diversity and Inequality

By the early school years, children absorb prevailing societal attitudes, associating power and privilege with white people and poverty and inferior status with people of color. They do not necessarily acquire these views directly from parents or friends, whose attitudes often differ from their own (Aboud & Doyle, 1996; Pahlke, Bigler, & Suizzo, 2012). Rather, children seem to pick up mainstream beliefs from implicit messages in the media and elsewhere in their environments. Powerful sources include social contexts that present a world sorted into groups, such as racial and ethnic segregation in schools and communities.

**In-Group and Out-Group Biases: Development of Prejudice.** Studies in diverse Western nations confirm that by age 5 to 6, white children generally evaluate their own racial group favorably and other racial groups less favorably or negatively. *In-group favoritism* emerges first; children simply prefer their own group, generalizing from self to similar others (Buttelmann & Böhm, 2014; Dunham, Baron, & Carey, 2011; Nesdale et al., 2004).

The ease with which a trivial group label supplied by an adult can induce in-group favoritism is striking. In one study, European-American 5-year-olds were told that they were members of a group based on T-shirt color. Although no information was provided about group status and the children never met any group members, they still displayed vigorous in-group favoritism (Dunham, Baron, & Carey, 2011). When shown photos of unfamiliar age mates wearing either an in-group or an out-group shirt, the children claimed to like members of their own group better, gave them more resources, and engaged in positively biased recall of group members’ behavior.

*Out-group prejudice* requires a more challenging social comparison between in-group and out-group. But it does not take long for white children to acquire negative attitudes toward ethnic minority out-groups when such attitudes are encouraged by circumstances in their environments. When white Canadian 4- to 7-year-olds living in a white community and attending nearly all-white schools sorted positive and negative adjectives into boxes labeled as belonging to a white child and a black child, out-group prejudice emerged at age 5 (Corenblum, 2003). Unfortunately, many minority children show a reverse pattern: *out-group favoritism*, in which they assign positive characteristics to the privileged white majority and negative characteristics to their own group (Averhart & Bigler, 1997; Newheiser et al., 2014).

But recall that with age, children pay more attention to inner traits. The capacity to classify the social world in multiple ways enables school-age children to understand that people can be both “the same” and “different”—those who look different need not think, feel, or act differently. Consequently, voicing of negative attitudes toward minorities declines after age 7 or 8 (Aboud, 2008; Raabe & Beelmann, 2011). Around this time, both majority and minority children express *in-group favoritism*, and white children’s *prejudice against out-group members* often weakens (Nesdale et al., 2005; Ruble et al., 2004).

Yet even in children aware of the injustice of discrimination, prejudice often operates unintentionally and without awareness—as it does in many adults (Dunham, Baron, & Banaji, 2006). Consider a study in which U.S. children and adults were shown pictures of computer-generated racially ambiguous faces displaying happy and angry expressions and asked to classify them by race. White participants more often categorized happy faces as white and angry faces as African American or Asian. These implicit biases were evident across all ages tested—as early as 3 or 4. In contrast, African-American participants did not show any racial biases in their responses (Dunham, Chen, & Banaji, 2013). The absence of any in-group favoritism (classifying happy faces as black) suggests an early-emerging, implicit sensitivity to prevailing racial attitudes among African Americans.

These findings raise the question of whether the decline in white children’s explicit racial bias during middle childhood is a true decrease or whether it reflects their growing awareness of widely held standards that deem prejudice to be inappropriate—or both. Around age 10, white children start to avoid talking about race in order to appear unbiased, just as many adults do (Apfelbaum et al., 2008). At least to some degree, then, older school-age children’s desire to present themselves in a socially

© JOEL ARTISTA

Palestinian and Israeli children and adolescents take a break from mural painting to sing and dance together. Intergroup contact, in which racially and ethnically different children have equal status, work toward common goals, and become personally acquainted, is an effective way to reduce prejudice.

acceptable light may contribute to reduced explicit out-group prejudice, while implicit racial bias persists.

Nevertheless, the extent to which children hold racial and ethnic biases varies, depending on the following personal and situational factors:

- *A fixed view of personality traits.* Children who believe that people's personality traits are fixed rather than changeable often judge others as either "good" or "bad." Ignoring motives and circumstances, they readily form prejudices based on limited information. For example, they might infer that "a new child at school who tells a lie to get other kids to like her" is simply "a bad kid" (Levy & Dweck, 1999).
- *Overly high self-esteem.* Children (and adults) with very high self-esteem are more likely to hold racial and ethnic prejudices (Baumeister et al., 2003; Bigler, 2013). These individuals seem to belittle disadvantaged people or groups to justify their own extremely favorable, yet insecure, self-evaluations. Children who say their own ethnicity makes them feel especially "good"—and thus perhaps socially superior—are more likely to display in-group favoritism and out-group prejudice (Pfeifer et al., 2007).
- *A social world in which people are sorted into groups.* The more adults highlight group distinctions and the less interracial contact children experience, the more likely white children will express in-group favoritism and out-group prejudice (Aboud & Brown, 2013).

**Reducing Prejudice.** Research confirms that an effective way to reduce prejudice is through intergroup contact, in which racially and ethnically different children have equal status, work toward common goals, and become personally acquainted, and in which parents and teachers expect them to engage in such interaction (Tropp & Page-Gould, 2015). Children assigned to cooperative learning groups with peers of diverse backgrounds

show low levels of prejudice in their expressions of likability and in their behavior. For example, they form more cross-race friendships (Pettigrew & Tropp, 2006). Sharing thoughts and feelings with close, cross-race friends, in turn, reduces even subtle, unintentional prejudices (Turner, Hewstone, & Voci, 2007). But positive effects seem not to generalize to out-group members who are not part of these learning teams.

Long-term contact and collaboration among neighborhood, school, and community groups may be the best way to reduce prejudice (Rutland, Killen, & Abrams, 2010). School environments that expose children to broad ethnic diversity, teach them to understand and value those differences, directly address the damage caused by prejudice, emphasize moral values of justice and fairness, and encourage perspective taking and empathy both prevent children from forming negative biases and lessen already acquired biases (Beelmann & Heinemann, 2014). Unfortunately, as noted in Chapter 9, segregation is widespread in U.S. schools, which seldom offer exposure to the diversity necessary for countering negative racial and ethnic biases. Return to page 327 to review efforts of magnet schools to reduce this racial divide.

Finally, inducing children to view others' traits as changeable, by discussing with them the many possible influences on those traits, is helpful. The more children believe that people can change their personalities, the more they report liking and perceiving themselves as similar to members of disadvantaged out-groups. Furthermore, children who believe that human attributes are changeable spend more time volunteering to help people in need (Karafantis & Levy, 2004). Volunteering may, in turn, promote a view of others as changeable by helping children take the perspective of the underprivileged and appreciate the social conditions that lead to disadvantage.

## Ask yourself

**CONNECT** Cite examples of how older children's capacity to take more information into account enhances their emotional and moral understanding.

**APPLY** Ten-year-old Marla says her classmate Bernadette will never get good grades because she's lazy. Jane believes that Bernadette tries but can't concentrate because her parents are divorcing. Why is Marla more likely than Jane to develop prejudices?

**REFLECT** Did you attend an integrated elementary school? Why is school integration vital for reducing racial and ethnic prejudice?

## Peer Relations

**10.5** How do peer sociability and friendship change in middle childhood?

**10.6** Describe major categories of peer acceptance and ways to help rejected children.

In middle childhood, the society of peers becomes an increasingly important context for development. The capacity for

recursive perspective taking permits more sophisticated understanding of self and others, which, in turn, contributes to peer interaction. Compared with preschoolers, school-age children resolve conflicts more effectively, using persuasion and compromise (Mayeux & Cillessen, 2003). Sharing, helping, and other prosocial acts also increase. In line with these changes, aggression declines. But the drop is greatest for physical attacks (Côté et al., 2007). As we will see, verbal and relational aggression continue as children organize into peer groups.

## Peer Groups

By the end of middle childhood, children display a strong desire for group belonging. They form **peer groups**, collectives that generate unique values and standards for behavior and a social structure of leaders and followers. Peer groups organize on the basis of proximity (being in the same classroom) and similarity in sex, ethnicity, academic achievement, popularity, and aggression (Rubin et al., 2013).

The practices of these informal groups lead to a “peer culture” that typically involves a specialized vocabulary, dress code, and place to “hang out.” As children develop these exclusive associations, the codes of dress and behavior that grow out of them become more broadly influential. Peers who deviate—by “kissing up” to teachers, wearing the wrong clothes, or tattling on classmates—are often rebuffed, becoming targets of critical glances and comments. These customs bind peers together, creating a sense of group identity. Within the group, children acquire many social skills—cooperation, leadership, followership, and loyalty to collective goals.

Most school-age children believe a group is wrong to exclude a peer on the basis of unconventional appearance or behavior—a view that strengthens with age (Killen, Crystal, & Watanabe, 2002). Nevertheless, children do exclude, often using relationally

aggressive tactics. Peer groups—at the instigation of their leaders, who can be skillfully aggressive—frequently oust no longer “respected” children. Some of these castouts, whose own previous behavior toward outsiders reduces their chances of being included elsewhere, turn to other low-status peers with poor social skills (Farmer et al., 2010). Socially anxious children, when ousted, often become increasingly peer-avoidant and thus more isolated (Buhs, Ladd, & Herald-Brown, 2010). In either case, opportunities to acquire socially competent behavior diminish.

School-age children’s desire for group membership can also be satisfied through formal group ties such as scouting, 4-H, and religious youth groups. Adult involvement holds in check the negative behaviors associated with children’s informal peer groups. And through working on joint projects and helping in their communities, children gain in social and moral maturity (Vandell & Shumow, 1999).

## Friendships

Whereas peer groups provide children with insight into larger social structures, friendships contribute to the development of trust and sensitivity. During the school years, friendship becomes more complex and psychologically based. Consider the following 8-year-old’s ideas:

*Why is Shelly your best friend?* Because she helps me when I’m sad, and she shares. . . . *What makes Shelly so special?* I’ve known her longer, I sit next to her and got to know her better. . . . *How come you like Shelly better than anyone else?* She’s done the most for me. She never disagrees, she never eats in front of me, she never walks away when I’m crying, and she helps me with my homework. . . . *How do you get someone to like you?* . . . If you’re nice to [your friends], they’ll be nice to you. (Damon, 1988b, pp. 80–81)

As these responses show, friendship has become a mutually agreed-on relationship in which children like each other’s personal qualities and respond to one another’s needs and desires. And once a friendship forms, *trust* becomes its defining feature. School-age children state that a good friendship is based on acts of kindness, signifying that each person can be counted on to support the other (Hartup & Abecassis, 2004). Consequently, older children regard violations of trust, such as not helping when others need help, breaking promises, and gossiping behind the other’s back, as serious breaches of friendship.

Because of these features, school-age children’s friendships are more selective. Whereas preschoolers say they have lots of friends, by age 8 or 9, children name only a handful of good friends. Girls, who demand greater closeness than boys, are more exclusive in their friendships. In addition, children tend to select friends similar to themselves in age, sex, race, ethnicity, and SES. Friends also resemble one another in personality (sociability, inattention/hyperactivity, aggression, depression), peer popularity, academic achievement, and prosocial behavior (Rubin et al., 2013). But friendship opportunities encouraged by children’s environments also affect their choices. Children whose parents have cross-race friends form more cross-race friendships

© BJARKI REYR MR/ALAMY

Peer groups first form in middle childhood. These boys have probably established a peer-group structure of leaders and followers as they gather for a soccer game. Their relaxed body language and similar dress suggest a strong sense of group belonging.

© KLAUS-PETER WOLFF/ROBERT HARDING

School-age children tend to select friends who are similar to themselves in personality and academic achievement. And friendships are fairly stable: These boys are likely to remain friends for at least a full school year.

(Pahlke, Bigler, & Suizzo, 2012). And as noted earlier, in integrated classrooms with mixed-race collaborative learning groups, students develop more cross-race friendships.

### LOOK and LISTEN

Ask an 8- to 11-year-old to tell you what he or she looks for in a best friend. Is *trust* centrally important? Does the child mention personality traits, just as school-age children do in describing themselves?

Over middle childhood, high-quality friendships remain fairly stable. About 50 to 70 percent endure over a school year, and some last for several years. Gains in friendship support—including compromise, sharing of thoughts and feelings, and prosocial behavior—contribute to this stability (Berndt, 2004; Furman & Rose, 2015). But context is also influential: Friendships spanning several situations—such as school, religious institution, and children of parents’ friends—are more likely to endure (Troutman & Fletcher, 2010).

Through friendships, children learn the importance of emotional commitment. They come to realize that close relationships can survive disagreements if friends are secure in their liking for each other and resolve disputes in ways that meet both partners’ needs. Yet the impact of friendships on children’s development depends on the nature of those friends. Children who bring kindness and compassion to their friendships strengthen each other’s prosocial tendencies.

But when aggressive children make friends, the relationship is often riddled with hostile exchanges and is at risk for breakup, especially when just one member of the pair is aggressive. And within these close ties, children’s aggressive tendencies worsen (Ellis & Zabatany, 2007; Salmivalli, 2010). Aggressive girls’ friendships are high in exchange of private feelings but also full of jealousy, conflict, and betrayal. Aggressive boys’ friendships involve frequent expressions of anger, coercive statements,

physical attacks, and enticements to rule-breaking behavior (Rubin et al., 2013; Werner & Crick, 2004). As we will see next, aggressive children often acquire negative reputations in the wider world of peers.

## Peer Acceptance

**Peer acceptance** refers to likability—the extent to which a child is viewed by a group of agemates, such as classmates, as a worthy social partner. Unlike friendship, likability is not a mutual relationship but a one-sided perspective, involving the group’s view of an individual. Nevertheless, better-accepted children tend to be socially competent and, as a result, have more friends and more positive relationships with them (Mayeux, Houser, & Dyches, 2011).

To assess peer acceptance, researchers usually use self-reports that measure *social preferences*—for example, asking children to identify classmates whom they “like most” or “like least” (Cillessen, 2009). These self-reports yield five general categories of peer acceptance:

- **Popular children**, who get many positive votes (are well-liked)
- **Rejected children**, who get many negative votes (are disliked)
- **Controversial children**, who receive many votes, both positive and negative (are both liked and disliked)
- **Neglected children**, who are seldom mentioned, either positively or negatively
- **Average children**, who receive average numbers of positive and negative votes and account for about one-third of children in a typical elementary school classroom

Another approach assesses *perceived popularity*—children’s judgments of whom most of their classmates admire. Only moderate correspondence exists between the classmates children perceive as popular (believe are admired by many others) and those classified as popular based on peer preferences (receive many “like most” ratings) (Mayeux, Houser, & Dyches, 2011).

Peer acceptance is a powerful predictor of psychological adjustment. Rejected children, especially, are anxious, unhappy, disruptive, and low in self-esteem. Both teachers and parents rate them as having a wide range of emotional and social problems. Peer rejection in middle childhood is also strongly associated with poor school performance, absenteeism, dropping out, substance use, depression, antisocial behavior, and delinquency in adolescence and with criminality in adulthood (Ladd, 2005; Rubin et al., 2013).

However, earlier influences—children’s characteristics combined with parenting practices—may largely explain the link between peer acceptance and adjustment. School-age children with peer-relationship problems are more likely to have weak emotional self-regulation skills and to have experienced family stress due to low income and insensitive parenting, including coercive discipline (Blair et al., 2014; Trentacosta & Shaw, 2009). Nevertheless, as we will see, rejected children evoke reactions from peers that contribute to their unfavorable development.

**Determinants of Peer Acceptance.** Why is one child liked while another is rejected? A wealth of research reveals that social behavior plays a powerful role.

**Popular Children.** **Popular-prosocial children** are both well-liked (socially preferred) and admired (high in perceived popularity). They combine academic and social competence, performing well in school and communicating with peers in friendly and cooperative ways (Cillessen & Bellmore, 2004; Mayeux, Houser, & Dyches, 2011).

But other popular children are admired for their socially adept yet belligerent behavior. **Popular-antisocial children** include “tough” boys—athletically skilled but poor students who cause trouble and defy adult authority—and relationally aggressive boys and girls who enhance their own status by ignoring, excluding, and spreading rumors about other children (Rose, Swenson, & Waller, 2004; Vaillancourt & Hymel, 2006). Despite their aggressiveness, peers often view these youths as “cool,” perhaps because of their athletic abilities and sophisticated but devious social skills. Although peer admiration gives these children some protection against lasting adjustment difficulties, their antisocial acts require intervention (Rodkin et al., 2006). With age, peers like these high-status, aggressive youths less and less, eventually condemning their nasty tactics and rejecting them.

**Rejected Children.** Rejected children display a wide range of negative social behaviors. The largest subtype, **rejected-aggressive children**, show high rates of conflict, physical and relational aggression, and hyperactive, inattentive, and impulsive behavior. They are usually deficient in perspective taking, misinterpreting the innocent behaviors of peers as hostile and blaming others for their social difficulties (Dodge, Coie, & Lynam, 2006; Rubin et al., 2013). Compared with popular-antisocial children, they are more extremely antagonistic.

In contrast, **rejected-withdrawn children** are passive and socially awkward. Overwhelmed by social anxiety, they hold negative expectations about interactions with peers and worry about being scorned and attacked (Rubin et al., 2013; Troop-Gordon & Asher, 2005).

Rejected children are excluded by peers as early as kindergarten. Soon their classroom participation declines, their feelings of loneliness rise, their academic achievement falters, and they want to avoid school (Buhs, Ladd, & Herald-Brown, 2010; Gooren et al., 2011). Most have few friends, and some have none—a circumstance that predicts severe adjustment difficulties (Ladd et al., 2011; Pedersen et al., 2007).

Both types of rejected children are at risk for peer harassment. But as the Biology and Environment box on the following page reveals, rejected-aggressive children also act as bullies, and rejected-withdrawn children are especially likely to be victimized.

## LOOK and LISTEN

Contact a nearby elementary school or a school district to find out what practices are in place to prevent bullying. Inquire about a written antibullying policy, and request a copy.

**Controversial and Neglected Children.** Consistent with the mixed peer opinion they engender, controversial children display a blend of positive and negative social behaviors. They are hostile and disruptive, but they also engage in positive, prosocial acts. Even though some peers dislike them, they have qualities that protect them from social exclusion. They have many friends and are happy with their peer relationships (de Bruyn & Cillessen, 2006). But like their popular-antisocial and rejected-aggressive counterparts, they often bully others and engage in calculated relational aggression to sustain their dominance (Putallaz et al., 2007).

Perhaps the most surprising finding on peer acceptance is that neglected children, once thought to be in need of treatment, are usually well-adjusted. Although they engage in low rates of interaction, most are just as socially skilled as average children and do not report feeling unhappy about their social life. When they want to, they can break away from their usual pattern of playing alone, cooperating well with peers and forming positive, stable friendships (Ladd & Burgess, 1999; Ladd et al., 2011). Neglected, socially competent children remind us that an outgoing, gregarious personality style is not the only path to emotional well-being.

**Helping Rejected Children.** A variety of interventions exist to improve the peer relations and psychological adjustment of rejected children. Most involve coaching, modeling, and reinforcing positive social skills, such as how to initiate interaction with a peer, cooperate in play, and respond to another child with friendly emotion and approval. Several of these programs have produced lasting gains in social competence and peer acceptance (Asher & Rose, 1997; DeRosier, 2007). Combining social-skills training with other treatments increases its effectiveness. Rejected children are often poor students, whose low academic self-esteem magnifies their negative interactions with teachers and classmates. Intensive academic tutoring improves both school achievement and social acceptance (O’Neill et al., 1997).

Still another approach focuses on training in perspective taking and in solving social problems. But many rejected-aggressive children are unaware of their poor social skills and do not take responsibility for their social failures (Mrug, Hoza, & Gerdes, 2001). Rejected-withdrawn children, in contrast, are likely to develop a *learned-helpless* approach to peer difficulties—concluding, after repeated rebuffs, that they will never be liked (Wichmann, Coplan, & Daniels, 2004). Both types of children need help attributing their peer difficulties to internal, changeable causes.

As rejected children gain in social skills, teachers must encourage peers to alter their negative opinions. Accepted children often selectively recall their negative acts while overlooking their positive ones (Mikami, Lerner, & Lun, 2010). Consequently, even in the face of contrary evidence, rejected children’s negative reputations tend to persist. Teachers’ praise and expressions of liking can modify peer judgments (De Laet et al., 2014).

Finally, because rejected children’s socially incompetent behaviors often originate in a poor fit between the child’s temperament and parenting practices, interventions focusing on the child alone may not be sufficient. Without improving the quality of parent–child interaction, rejected children may soon return to their old behavior patterns.

## Biology and Environment

### Bullies and Their Victims

Follow the activities of aggressive children over a school day, and you will see that they reserve their hostilities for certain peers. A particularly destructive form of interaction is **peer victimization**, in which certain children become targets of verbal and physical attacks or other forms of abuse. What sustains these repeated assault–retreat cycles between pairs of children? About 20 percent of children are bullies, while 25 percent are repeatedly victimized. Most bullies who engage in face-to-face physical and verbal attacks are boys, but a considerable number of girls bombard vulnerable classmates with verbal and relational hostility (Cook et al., 2010).

As bullies move into adolescence, an increasing number attack through electronic means. About 20 to 40 percent of youths have experienced “cyberbullying” through text messages, e-mail, social media sites, or other electronic tools (Kowalski & Limber, 2013). Compared with face-to-face bullying, gender differences in cyberbullying are less pronounced; the indirectness of online aggression may lead girls to prefer it (Menesini & Spiel, 2012). Girls more often cyberbully with words, whereas boys typically distribute embarrassing photos or videos.

Perpetrators and victims of “traditional” bullying are frequently involved in cyberbullying. But electronic bullying is not always an extension of traditional bullying (Smith et al., 2008). And victims are far less likely to report cyberbullying to parents or adults at school. In many instances, the cyberbully’s identity is unknown to the victim and audience.

Many bullies are disliked, or become so, because of their cruelty. But a substantial number are socially powerful youngsters who are broadly admired by peers. These high-status bullies often target already-peer-rejected children, whom classmates are unlikely to defend (Veenstra et al., 2010). Not only do peers rarely intervene to help victims, but about 20 to 30 percent of onlookers encourage bullies, even joining in (Salmivalli & Voeten, 2004).

Bullying occurs more often in schools where teachers are viewed as unfair and uncaring and where many students judge bullying behavior to be “OK” (Guerra, Williams, & Sadek, 2011). Indeed, bullies and the peers who assist

them typically display social information-processing deficits, including overly high self-esteem, pride in their acts, and indifference to harm done to their victims (Hymel et al., 2010).

Chronic victims tend to be passive when active behavior is expected. Biologically based traits—an inhibited temperament and a frail physical appearance—contribute. But victims also have histories of resistant attachment, overly controlling child rearing, and maternal overprotection—parenting that prompts anxiety, low self-esteem, and dependency, resulting in a fearful demeanor that marks these children as vulnerable (Snyder et al., 2003).

Consequences of victimization include loneliness, low peer acceptance, poor school performance, disruptive behavior, and school avoidance (Kochel, Ladd, & Rudolph, 2012; Paul & Cillessen, 2003). Like persistent child abuse, victimization is linked to impaired production of cortisol, suggesting a disrupted physiological response to stress (Vaillancourt, Hymel, & McDougall, 2013).

As instances of traditional bullying and cyberbullying accumulate, victims report substantial interference with daily functioning. Both traditional bullying and cyberbullying are related to rising anxiety, depression, and suicidal thoughts (Menesini, Calussi, & Nocentini, 2012; van den Eijnden et al., 2014). Repeated cyberattacks directed at causing widespread damage to the victim’s reputation—for example, circulating malicious videos on cell phones or social networking sites—magnify these effects.

Aggression and victimization are not polar opposites. One-third to one-half of victims are also aggressive, meting out physical, relational, or cyberhostilities. Bullies usually respond by abusing them again—a cycle that sustains their victim status. Among rejected children, these bully/victims are the most despised. They often have histories of

Bullies and the peers who assist them typically display overly high self-esteem, pride in their acts, and indifference to the harm done to their victims. And chronic victims are often easy targets—physically weak, passive, and inhibited.

extremely maladaptive parenting, including child abuse. This combination of highly negative home and peer experiences places them at severe risk for maladjustment (Kowalski, Limber, & Agatston, 2008).

Interventions that change victimized children’s negative opinions of themselves and that teach them to respond in nonreinforcing ways to their attackers are helpful. Another way to assist victimized children is to help them form and maintain a gratifying friendship (Fox & Boulton, 2006). When children have a close friend to whom they can turn for help, bullying episodes usually end quickly.

Although modifying victimized children’s behavior can help, the best way to reduce bullying is to promote prosocial attitudes and behaviors in youth environments (including school, sports programs, recreation centers, and neighborhoods). Effective approaches include developing school and community codes against both traditional bullying and cyberbullying; teaching child bystanders to intervene; strengthening parental oversight of children’s use of cell phones, computers, and the Internet; and increasing adult supervision of high-bullying areas in schools, such as hallways, lunchroom, and schoolyard (Kärnä et al., 2011; Kiriakidis & Kavoura, 2010).

The U.S. Department of Health and Human Services manages an antibullying website, [www.stopbullying.gov](http://www.stopbullying.gov), that raises awareness of the harmfulness of bullying and provides information on prevention.

## Gender Typing

**10.7** What changes in gender-stereotyped beliefs and gender identity occur during middle childhood?

Children's understanding of gender roles broadens in middle childhood, and their gender identities (views of themselves as relatively masculine or feminine) change as well. We will see how gender stereotypes influence children's attitudes, behaviors, peer relations, and self-perceptions.

### Gender-Stereotyped Beliefs

Research in many countries reveals that stereotyping of personality traits increases steadily in middle childhood, becoming adultlike around age 11 (Best, 2001; Heyman & Legare, 2004). For example, children regard "tough," "aggressive," "rational," and "dominant" as masculine and "gentle," "sympathetic," and "dependent" as feminine.

Children derive these distinctions from observing sex differences in behavior as well as from adult treatment. When helping a child with a task, for example, parents (especially fathers) behave in a more mastery-oriented fashion with sons, setting higher standards, explaining concepts, and pointing out important features of tasks—particularly during gender-typed pursuits, such as science activities (Tenenbaum & Leaper, 2003; Tenenbaum et al., 2005).

Furthermore, elementary school teachers tend to stereotype girls who display "feminine" behavior as diligent and compliant and boys who display "masculine" behavior as lazy and troublesome (Heyder & Kessels, 2015). These perceptions may contribute to boys' reduced academic engagement and lower school grades relative to girls'. At the same time, when teachers are presented with a boy and a girl who are equally successful at math, they tend to see the girl as having to work harder (Robinson-Cimpian et al., 2014). As we saw in our discussion of achievement-related attributions, this downrating of girls' ability negatively affects their performance.

Also in line with adult stereotypes, school-age children often regard reading, spelling, art, and music as subjects girls are good at and mathematics, athletics, and mechanical skills as subjects boys are good at (Cvencek, Meltzoff, & Greenwald, 2011; Eccles, Jacobs, & Harold, 1990). These attitudes influence children's preferences for and sense of competence at various subjects.

An encouraging sign is that children's gender-stereotyped beliefs about achievement may be changing. In several investigations carried out in Canada, France, and the United States, a majority of elementary and secondary students disagreed with the idea that math is a "masculine" subject (Kurtz-Costes et al., 2014; Martinot, Bagès, & Désert, 2012; Plante, Théoret, & Favreau, 2009; Rowley et al., 2007). The overwhelming majority of these young people, however, continued to view language arts traditionally—as largely "feminine." And they still perceived girls as doing better in language arts than in math.

Although school-age children are aware of many stereotypes, they also develop a more open-minded view of what males and females *can do*. As with racial stereotypes (see page 344), the ability to classify flexibly contributes to this change. School-age children realize that a person's sex is not a certain predictor of his or her personality traits, activities, and behavior (Halim & Ruble, 2010; Trautner et al., 2005). Similarly, by the end of middle childhood, most children regard gender typing as socially rather than biologically influenced (Taylor, Rhodes, & Gelman, 2009).

Nevertheless, acknowledging that people *can* cross gender lines does not mean that children always *approve* of doing so. In one longitudinal study, between ages 7 and 13, children generally became more open-minded about girls being offered the same opportunities as boys (Crouter et al., 2007). But this change was less pronounced for boys than girls, and for children whose parents held more traditional gender attitudes. Furthermore, many school-age children take a harsh view of certain violations—boys playing with dolls and wearing girls' clothing, girls acting noisily and roughly (Blakemore, 2003). They are especially intolerant when boys engage in these "cross-gender" acts.

### Gender Identity and Behavior

Children who were more strongly gender-typed relative to their agetates in early childhood usually remain so in middle childhood (Golombok et al., 2008). Nevertheless, overall changes do occur, with boys' and girls' gender identities following different paths.

From third to sixth grade, boys tend to strengthen their identification with "masculine" personality traits, whereas girls' identification with "feminine" traits declines. While still leaning toward the "feminine" side, girls are more *androgynous* than boys—more likely to describe themselves as having some

An 8-year-old launches the rocket she made in her school's Young Astronaut Club. Whereas school-age boys usually stick to "masculine" pursuits, girls experiment with a wider range of options.

“other-gender” characteristics (Serbin, Powlishta, & Gulko, 1993). And whereas boys usually stick to “masculine” pursuits, many girls experiment with a wider range of options—from cooking and sewing to sports and science projects—and more often consider traditionally male future work roles, such as firefighter or astronomer (Liben & Bigler, 2002).

These changes are due to a mixture of cognitive and social forces. School-age children of both sexes are aware that society attaches greater prestige to “masculine” characteristics. For example, they rate “masculine” occupations as having higher status than “feminine” occupations and an unfamiliar job as higher in status when portrayed with a male worker than a female worker (Liben, Bigler, & Krogh, 2001; Weisgram, Bigler, & Liben, 2010). Messages from adults and peers are also influential. In Chapter 8, we saw that parents (especially fathers) are more disapproving when sons, as opposed to daughters, cross gender lines. Similarly, a tomboyish girl can interact with boys without losing the approval of her female peers, but a boy who hangs out with girls is likely to be ridiculed and rejected.

As school-age children make social comparisons and characterize themselves in terms of stable dispositions, their gender identity expands to include the following self-evaluations, which greatly affect their adjustment:

- *Gender typicality*—the degree to which the child feels similar to others of the same gender. Although children need not be highly gender-typed to view themselves as gender-typical, their psychological well-being depends, to some degree, on feeling that they “fit in” with their same-sex peers.
- *Gender contentedness*—the degree to which the child feels comfortable with his or her gender assignment, which also promotes happiness.
- *Felt pressure to conform to gender roles*—the degree to which the child feels parents and peers disapprove of his or her gender-related traits. Because such pressure reduces the likelihood that children will explore options related to their interests and talents, children who feel strong gender-typed pressure are often distressed.

In a longitudinal study of third through seventh graders, gender-typical and gender-contented children gained in self-esteem over the following year, whereas gender-atypical and gender-discontented children declined in self-worth. Furthermore, *gender-atypical* children, especially those who report *intense pressure to conform to gender roles*, experience serious adjustment difficulties—withdrawal, sadness, disappointment, and anxiety (Corby, Hodges, & Perry, 2007; Yunger, Carver, & Perry, 2004). Clearly, school-age children who experience rejection because of their gender-atypical traits suffer profoundly.

Because felt pressure to conform to gender roles predicts maladjustment among gender-atypical children, more experts are advocating interventions that help parents and peers become more accepting of children’s gender-atypical interests and behaviors (Bigler, 2007; Conway, 2007; Hill et al., 2010). Return to page 281 in Chapter 8 to review related evidence on gender-dysphoric children, who feel profoundly discontented with their

natal (birth) sex and who strongly identify as the other sex, along with evidence on the best therapeutic approach to help them.

## Ask yourself

**CONNECT** Describe similarities in development of self-concept, attitudes toward racial and ethnic minorities, and gender-stereotyped beliefs in middle childhood.

**APPLY** What changes in parent–child and teacher–child relationships are likely to help rejected children?

**REFLECT** As a school-age child, did you have classmates you would classify as popular-antisocial? What were they like, and why do you think peers admired them?

## Family Influences

**10.8** How do parent–child communication and sibling relationships change in middle childhood?

**10.9** What factors influence children’s adjustment to divorce and blended family arrangements?

**10.10** How do maternal employment and life in dual-earner families affect school-age children?

As children move into school, peer, and community contexts, the parent–child relationship changes. At the same time, children’s well-being continues to depend on the quality of family interaction. In the following sections, we will see that contemporary diversity in family life—divorce, remarriage, maternal employment, and dual-earner families—can have positive as well as negative effects on children. In later chapters, we take up other family structures, including gay and lesbian families, never-married single-parent families, and the increasing numbers of grandparents rearing grandchildren.

## Parent–Child Relationships

In middle childhood, the amount of time children spend with parents declines dramatically. Children’s growing independence means that parents must deal with new issues. “I’ve struggled with how many chores to assign, how much allowance to give, whether their friends are good influences, and what to do about problems at school,” Rena remarked. “And then there’s the challenge of keeping track of them when they’re out—or even when they’re home and I’m not there to see what’s going on.”

Despite these new concerns, child rearing becomes easier for parents who established an authoritative style during the early years. Reasoning is more effective with school-age children because of their greater capacity for logical thinking and their increased respect for parents’ expert knowledge. And children of parents who engage in joint decision making where possible are more likely to listen to parents’ perspectives in situations where compliance is vital (Russell, Mize, & Bissaker, 2004).

As children demonstrate that they can manage daily activities and responsibilities, effective parents gradually shift control from adult to child. They do not let go entirely but, rather, engage in **coregulation**, a form of supervision in which they exercise general oversight while letting children take charge of moment-by-moment decision making. Coregulation grows out of a warm, cooperative relationship between parent and child based on give-and-take. Parents must guide and monitor from a distance and effectively communicate expectations when they are with their children. And children must inform parents of their whereabouts, activities, and problems so parents can intervene when necessary (Collins, Madsen, & Susman-Stillman, 2002). Coregulation supports and protects children while preparing them for adolescence, when they will make many important decisions themselves.

As at younger ages, mothers tend to spend more time than fathers with school-age children and know more about children's everyday activities, although many fathers are highly involved (Pew Research Center, 2015e). Both parents, however, tend to devote more time to children of their own sex (Lam, McHale, & Crouter, 2012). And parents are more vigilant about monitoring the activities of same-sex children while their children are away from home.

Although school-age children often press for greater independence, they know how much they need their parents' support. A positive parent-child relationship is linked to improved emotional self-regulation in children, reducing the negative impact of stressful events (Brumariu, Kerns, & Seibert, 2012; Hazel et al., 2014). School-age children often turn to parents for affection, advice, affirmation of self-worth, and assistance with everyday problems.

## Siblings

In addition to parents and friends, siblings continue to be important sources of support. Yet sibling rivalry tends to increase in middle childhood. As children participate in a wider range of activities, parents often compare siblings' traits and accomplishments. The child who gets less parental affection, more disapproval, or fewer material resources is likely to be resentful and show poorer adjustment (Dunn, 2004b; McHale, Updegraff, & Whiteman, 2012).

For same-sex siblings who are close in age, parental comparisons are more frequent, resulting in more quarreling and antagonism. This effect is particularly strong when parents are under stress as a result of financial worries, marital conflict, single parenthood, or child negativity (Jenkins, Rasbash, & O'Connor, 2003). Parents whose energies are drained become less careful about being fair. Perhaps because fathers, overall, spend less time with children than mothers, children react especially intensely when fathers prefer one child (Kolak & Volling, 2011).

To reduce rivalry, siblings often strive to be different from one another (McHale, Updegraff, & Whiteman, 2012). For example, two brothers I know deliberately selected different athletic pursuits and musical instruments. If the older one did

© SHEHZAD NOORANI/DRIK/MAJORITY WORLD/THE IMAGE WORKS

An older sister helps her 6-year-old brother with homework. Although sibling rivalry tends to increase in middle childhood, siblings also provide each other with emotional support and help with difficult tasks.

especially well at an activity, the younger one did not want to try it. Parents can limit these effects by making an effort not to compare children, but some feedback about their competencies is inevitable. As siblings strive to win recognition for their own uniqueness, they shape important aspects of each other's development.

Although conflict rises, school-age siblings continue to rely on each other for companionship, assistance, and emotional support. But for siblings to reap these benefits, parental encouragement of warm, considerate sibling ties is vital. The more positive their relationship, the more siblings resolve disagreements constructively, provide help with family, academic, and peer challenges, and contribute to resilience in the face of major stressors, such as parental divorce (Conger, Stocker, & McGuire, 2009; Soli, McHale, & Feinberg, 2009).

When siblings get along well, the older sibling's academic and social competence tends to "rub off on" the younger sibling, fostering more favorable achievement and peer relations. And both older and younger siblings benefit in empathy and prosocial behavior (Brody & Murry, 2001; Lam, Solmeyer, & McHale, 2012; Padilla-Walker, Harper, & Jensen, 2010). But destructive sibling conflict in middle childhood is associated with negative outcomes, including conflict-ridden peer relationships, anxiety, depressed mood, and later substance use and delinquency, even after other family relationship factors are controlled (Kim et al., 2007; Ostrov, Crick, & Stauffacher, 2006).

## Only Children

Although sibling relationships bring many benefits, they are not essential for healthy development. Contrary to popular belief, only children are not spoiled, and in some respects, they are advantaged. U.S. children growing up in one-child and multi-child families do not differ in self-rated personality traits (Mottus, Indus, & Allik, 2008). And compared to children with siblings, only children are higher in self-esteem and achievement motivation, do better in school, and attain higher levels of education. One reason may be that only children have somewhat closer

relationships with parents, who may exert more pressure for mastery and accomplishment and can invest more time in their child's educational experiences (Falbo, 2012). However, only children tend to be less well-accepted in the peer group, perhaps because they have not had opportunities to learn effective conflict-resolution strategies through sibling interactions (Kitzmann, Cohen, & Lockwood, 2002).

Favorable development also characterizes only children in China, where a one-child family policy was enforced in urban areas for more than three decades, until it was abolished in 2015. Compared with age-mates who have siblings, Chinese only children are slightly advantaged in cognitive development and academic achievement. They also feel more emotionally secure, perhaps because government disapproval led to tension in families with more than one child (Falbo, 2012; Yang et al., 1995). Chinese mothers usually ensure that their children have regular contact with first cousins (who are considered siblings). Perhaps as a result, Chinese only children do not differ from age-mates with siblings in social skills and peer acceptance (Hart, Newell, & Olsen, 2003).

## Divorce

Children's interactions with parents and siblings are affected by other aspects of family life. When Joey was 8 and Lizzie 5, their father, Drake, moved out. During the preceding months, Joey began pushing, hitting, taunting, and calling Lizzie names. Although she tried to retaliate, she was no match for Joey's larger size. The arguments usually ended with Lizzie running in tears to her mother. Joey and Lizzie's fighting coincided with their parents' growing marital unhappiness.

Between 1960 and 1985, divorce rates in Western nations rose dramatically before stabilizing in most countries. The United States has experienced a decline in divorce over the past twenty years, largely due to a rise in age at first marriage and a drop in marriage rates. However, this decrease largely applies to well-educated, financially secure families. As Figure 10.3 shows, individuals with less education experience substantially greater marital instability (Lundberg & Pollak, 2015). Because educational and economic disadvantage increases family fragility, divorce rates are higher among African Americans, Hispanic Americans, and Native Americans than among European Americans (Raley, Sweeny, & Wondra, 2015).

Among developed nations, the United States has one of the highest divorce rates. Of the estimated 42 to 45 percent of American marriages that end in divorce, half involve children. More than one-fourth of U.S. children live in divorced, single-parent households. Although most reside with their mothers, the percentage in father-headed households has increased steadily, to about 14 percent (U.S. Census Bureau, 2015d).

Children of divorce spend an average of five years in a single-parent home—almost a third of childhood. For many, divorce leads to new family relationships. About 10 percent of U.S.

**FIGURE 10.3 Divorce rates among U.S. women by level of education.** A survey of over 10,000 U.S. women between ages 15 and 44 revealed that increased education is linked to marital stability, limited education to divorce, remarriage, and subsequent divorce. (Based on Lundberg & Pollak, 2015.)

children live with one parent (usually their mother) and a married or cohabiting stepparent (Kreider & Ellis, 2011). Many of these children eventually experience a third major change—the end of their parent's second marriage or cohabiting partnership.

These figures reveal that divorce is not a single event in the lives of parents and children. Instead, it is a transition that leads to a variety of new living arrangements, accompanied by changes in housing, income, and family roles and responsibilities. Although divorce is stressful for children and increases the risk of adjustment problems, most adjust favorably (Greene et al., 2012; Lamb, 2012). How well children fare depends on many factors: the custodial parent's psychological health and financial resources, the child's characteristics, and social supports within the family and surrounding community.

**Immediate Consequences.** “Things were worst after Drake and I decided to separate,” Rena reflected. “We fought over division of our belongings and custody of the children, and the kids suffered. Sobbing, Lizzie told me she was ‘sorry she made Daddy go away.’ Joey kicked and threw things at home and didn’t do his work at school. In the midst of everything, I could hardly deal with their problems. We had to sell the house, and I needed a better-paying job.”

Family conflict often rises in newly divorced households as parents try to settle disputes over children and possessions. Once one parent moves out, additional events threaten supportive interactions between parents and children. Mother-headed households typically experience a sharp drop in income. In the United States, nearly 30 percent of divorced mothers with young children live in poverty, and many more are low-income, getting less than the full amount of child support from the absent father or

none at all (U.S. Census Bureau, 2011). They often have to move to lower-cost housing, reducing supportive ties to neighbors and friends.

The transition from marriage to divorce typically leads to high maternal stress, depression, and anxiety and to a disorganized family life. Declines in well-being are greatest for mothers of young children (Williams & Dunne-Bryant, 2006). “Meals and bedtimes were at all hours, the house didn’t get cleaned, and I stopped taking Joey and Lizzie on weekend outings,” said Rena. As children react with distress and anger to their less secure home lives, discipline may become harsh and inconsistent. Over time, contact with noncustodial fathers—and quality of the father–child relationship—often decreases, particularly when parental conflict is high (Troilo & Coleman, 2012). Fathers who see their children only occasionally are inclined to be permissive and indulgent, making the mother’s task of managing the child even more difficult.

The more parents argue and fail to provide children with warmth, involvement, and consistent guidance, the poorer children’s adjustment. About 20 to 25 percent of children in divorced families display severe problems, compared with about 10 percent in nondivorced families (Golombok & Tasker, 2015; Lansford, 2009). At the same time, reactions vary with children’s age, temperament, and sex.

**Children’s Age.** Preschool and young school-age children often blame themselves for a marital breakup and fear that both parents may abandon them. And although older children have the cognitive maturity to understand that they are not responsible for their parents’ divorce, many react strongly, declining in school performance, becoming unruly, and escaping into undesirable peer activities, especially when family conflict is high and parental supervision is low (Kleinsorge & Covitz, 2012; Lansford et al., 2006). Some older children—especially the oldest child in the family—display more mature behavior, willingly taking on extra household tasks, care of younger siblings, and emotional support of a depressed, anxious mother. But if these demands are too great, these children may eventually become resentful, withdraw from the family, and engage in angry, acting-out behavior (Hetherington & Kelly, 2002).

**Children’s Temperament and Sex.** Exposure to stressful life events and inadequate parenting magnifies the problems of temperamentally difficult children (see Chapter 6). In contrast, easy children are less often targets of parental anger and also cope more effectively with adversity.

These findings help explain sex differences in response to divorce. Girls sometimes respond as Lizzie did, with internalizing reactions such as crying, self-criticism, and withdrawal. More often, children of both sexes show demanding, attention-getting behavior. But in mother-custody families, boys are at slightly greater risk for serious adjustment problems (Amato, 2010). Recall from Chapter 8 that boys are more active and non-compliant—behaviors that increase with exposure to parental conflict and inconsistent discipline. Coercive maternal behavior and defiance by sons are common in divorcing households.

**Long-Term Consequences.** Rena eventually found better-paying work and gained control over the daily operation of the household. And after several meetings with a counselor, Rena and Drake realized the harmful impact of their quarreling on Joey and Lizzie. Drake visited regularly and handled Joey’s unruliness with firmness and consistency. Soon Joey’s school performance improved, his behavior problems subsided, and both children seemed calmer and happier.

Most children show improved adjustment by two years after divorce. Yet overall, children and adolescents of divorced parents continue to score slightly lower than children of continuously married parents in academic achievement, self-esteem, social competence, and emotional and behavior problems (Lansford, 2009; Weaver & Schofield, 2015). And divorce is linked to problems with adolescent sexuality and development of intimate ties. Young people who experienced parental divorce—especially more than once—display higher rates of early sexual activity and adolescent parenthood. Some show other lasting difficulties—reduced educational attainment, troubled romantic relationships and marriages, divorce in adulthood, and unsatisfying parent–child relationships (Amato, 2010).

The overriding factor in positive adjustment following divorce is effective parenting—shielding the child from family conflict and using authoritative child rearing (Lamb, 2012). Parent-training programs can help custodial parents support their children’s development. One eleven-session parent-training intervention for mothers of school-age children yielded improved parent–child relationships and child coping skills, with effects persisting for six years (Velez et al., 2011).

Where the custodial parent is the mother, regular contact with fathers is also important. But only about one-third of children experience at least weekly visits (Amato & Dorius, 2010). The more paternal contact and the warmer the father–child relationship, the less children react with defiance and aggression (Dunn et al., 2004). For girls, a good father–child relationship protects against early sexual activity and unhappy romantic involvements. For boys, it seems to affect overall psychological

Regular contact with both parents and effective coparenting—supporting each other in their child-rearing roles—greatly improve adjustment in children of divorce.

## Applying what we Know

### Helping Children Adjust to Their Parents' Divorce

SUGGESTION	EXPLANATION
Shield children from conflict.	Witnessing intense parental conflict is very damaging to children. If one parent insists on expressing hostility, children fare better if the other parent does not respond in kind.
Provide children with as much continuity, familiarity, and predictability as possible.	Children adjust better during the period surrounding divorce when their lives have some stability—for example, the same school, bedroom, babysitter, playmates, and daily schedule.
Explain the divorce, and tell children what to expect.	Children may develop fears of abandonment if they are not prepared for their parents' separation. They should be told that their parents will not be living together anymore, which parent will be moving out, and when they will be able to see that parent. If possible, parents should explain the divorce together, providing a reason that each child can understand and assuring children that they are not to blame.
Emphasize the permanence of the divorce.	Fantasies of parents getting back together can prevent children from accepting the reality of their current life. Children should be told that the divorce is final and that they cannot change this fact.
Respond sympathetically to children's feelings.	Children need supportive, understanding responses to their feelings of sadness, fear, and anger. For children to adjust well, their painful emotions must be acknowledged, not denied or avoided.
Engage in authoritative parenting.	Authoritative parenting—providing affection and acceptance, reasonable demands for mature behavior, and consistent, rational discipline—greatly reduces children's risk of maladjustment following divorce.
Promote a continuing relationship with both parents.	When parents disentangle their lingering hostility toward the former spouse from the child's need for a continuing relationship with the other parent, children adjust well.

well-being. In fact, some studies report that outcomes for sons are better when the father is the custodial parent (Clarke-Stewart & Hayward, 1996; McLanahan, 1999). Fathers' greater economic security and image of authority seem to help them engage in effective parenting with sons. And boys in father-custody families may benefit from greater involvement of both parents because noncustodial mothers participate more in their children's lives than do noncustodial fathers.

Although divorce is painful for children, remaining in an intact but high-conflict family is much worse than making the transition to a low-conflict, single-parent household (Lamb, 2012; Strohschein, 2005). Divorcing parents who manage to engage in *effective coparenting* (see page 57 in Chapter 2), supporting each other in their child-rearing roles, greatly improve their children's chances of growing up competent, stable, and happy (Lamb, 2012). Caring extended-family members, teachers, siblings, and friends also reduce the likelihood that divorce will result in long-term difficulties (Hetherington, 2003).

#### Divorce Mediation, Joint Custody, and Child Support.

Awareness that divorce is highly stressful for children and families has led to community-based services aimed at helping them through this difficult time. One such service is *divorce mediation*, a series of meetings between divorcing adults and a trained professional aimed at reducing family conflict, including legal battles over property division and child custody. Mediation increases out-of-court settlements, cooperation and involvement of both parents in child rearing, and parents' and children's feelings of well-being (Douglas, 2006; Emery, Sbarra, & Grover, 2005).

*Joint custody*, which grants parents equal say in important decisions about the child's upbringing, is becoming increasingly common. Children usually reside with one parent and see the other on a fixed schedule, similar to the typical sole-custody situation. In other cases, parents share physical custody, and children move between homes. Joint-custody parents report little conflict—fortunately so, since the success of the arrangement depends on effective coparenting (Bauserman, 2012). And their children, regardless of living arrangements, tend to be better-adjusted than children in sole-maternal-custody homes (Bauserman, 2002).

Finally, many single-parent families depend on child support from the noncustodial parent to relieve financial strain. All U.S. states have procedures for withholding wages from parents who fail to make these payments. Although child support is usually not enough to lift a single-parent family out of poverty, it can ease its burdens substantially. Noncustodial fathers who have generous visitation schedules and who often see their children are more likely to pay child support regularly (Amato & Sobolewski, 2004). And increases in paternal contact and in child support over time predict better coparenting relationships (Hofferth, Forry, & Peters, 2010). Applying What We Know above summarizes ways to help children adjust to their parents' divorce.

### Blended Families

"If you get married to Wendell, and Daddy gets married to Carol," Lizzie wondered aloud to Rena, "then I'll have two sisters and one more brother. And let's see, how many grandmothers and grandfathers? A lot!" exclaimed Lizzie.

About 60 percent of divorced parents remarry within a few years. Others *cohabit*, or share a sexual relationship and a residence with a partner outside of marriage. Parent, stepparent, and children form a new family structure called the **blended, or reconstituted, family**. For some children, this expanded family network is positive, bringing greater adult attention. But children in blended families usually have more adjustment problems than children in stable, first-marriage families (Pryor, 2014). Switching to stepparents' new rules and expectations can be stressful, and children often view steprelatives as intruders. How well they adapt is, again, related to the quality of family functioning. This depends on which parent forms a new relationship, the child's age and sex, and the complexity of blended-family relationships. As we will see, older children and girls seem to have the hardest time.

**Mother–Stepfather Families.** Because mothers generally retain custody of children, the most common form of blended family is a mother–stepfather arrangement. Boys tend to adjust quickly, welcoming a stepfather who is warm, who refrains from exerting his authority too quickly, and who offers relief from coercive cycles of mother–son interaction. Mothers' friction with sons also declines as a result of greater economic security, another adult to share household tasks, and an end to loneliness (Visher, Visher, & Pasley, 2003). Stepfathers who marry rather than cohabit are more involved in parenting, perhaps because men who choose to marry a mother with children are more interested in and skilled at child rearing (Hofferth & Anderson, 2003). Girls, however, often have difficulty with their custodial mother's remarriage. Stepfathers disrupt the close ties many girls have established with their mothers, and girls often react with sulky, resistant behavior (Pryor, 2014).

But age affects these findings. Older school-age children and adolescents of both sexes display more irresponsible, acting-out behavior than their peers not in stepfamilies (Hetherington & Stanley-Hagan, 2000; Robertson, 2008). If parents are warmer and more involved with their biological children than with their stepchildren, older children are more likely to notice and challenge unfair treatment. And adolescents often view the new stepparent as a threat to their freedom, especially if they experienced little parental monitoring in the single-parent family. But when teenagers have affectionate, cooperative relationships with their mothers, many develop good relations with their stepfathers—a circumstance linked to more favorable adolescent well-being (King, 2009; Yuan & Hamilton, 2006).

**Father–Stepmother Families.** Remarriage of noncustodial fathers often leads to reduced contact with their biological children, especially when fathers remarry quickly, before they have established postdivorce parent–child routines (Dunn, 2002; Juby et al., 2007). When fathers have custody, children typically react negatively to remarriage. One reason is that children living with fathers often start out with more problems. Perhaps the biological mother could no longer handle the difficult child (usually a boy), so the father and his new partner are faced with the

child's behavior problems. In other instances, the father has custody because of a very close relationship with the child, and his remarriage disrupts this bond (Buchanan, Maccoby, & Dornbusch, 1996).

Girls, especially, have a hard time getting along with their stepmothers, either because the remarriage threatens the girl's bond with her father or because she becomes entangled in loyalty conflicts between the two mother figures. But the longer girls live in father–stepmother households, the more positive their interaction with stepmothers becomes (King, 2007). With time and patience, children of both genders benefit from the support of a second mother figure.

**Support for Blended Families.** Parenting education and couples counseling can help parents and children adapt to the complexities of blended families. Effective approaches encourage stepparents to move into their new roles gradually by first building a warm relationship with the child, which makes more active parenting possible (Pasley & Garneau, 2012). Counselors can offer couples guidance in effective coparenting to limit loyalty conflicts and provide consistency in child rearing. And tempering parents' unrealistic expectations for children's rapid adjustment—by pointing out that building a unified blended family often takes years—makes it easier for families to endure the transition and succeed.

Unfortunately, the divorce rate for second marriages is higher than for first marriages. Parents with antisocial tendencies and poor child-rearing skills are particularly likely to have several divorces and remarriages. The more marital transitions children experience, the greater their adjustment difficulties (Amato, 2010). These families usually require prolonged, intensive therapy.

## Maternal Employment and Dual-Earner Families

Today, U.S. single and married mothers are in the labor market in nearly equal proportions, and more than three-fourths of those with school-age children are employed (U.S. Census Bureau, 2015d). In previous chapters, we saw that the impact of maternal employment on early development depends on the quality of child care and the parent–child relationship. The same is true in middle childhood.

### Maternal Employment and Child Development.

When employed mothers remain committed to parenting, children develop favorably, displaying higher self-esteem and less gender-stereotyped beliefs. Girls, especially, perceive women's roles as involving more freedom of choice and satisfaction and are more career-oriented (Hoffman, 2000). Furthermore, stable maternal employment begun in early childhood is linked to higher achievement and fewer behavior problems in elementary school, especially for children of low-income mothers (Lombardi & Coley, 2013; Lucas-Thompson, Goldberg, & Prause, 2010). Parenting practices and improved financial well-being likely contribute to these benefits. Employed mothers who

feel economically more secure are more likely to engage in warm, involved parenting.

In dual-earner households, maternal employment often leads fathers to take on greater child-rearing responsibilities. Paternal involvement is associated in childhood and adolescence with higher achievement, more mature social behavior, and a flexible view of gender roles; and in adulthood with generally better mental health (Bornstein, 2015; Lamb & Lewis, 2013).

But when employment places heavy demands on parents' schedules or is stressful for other reasons, children are at risk for ineffective parenting (Strazdins et al., 2013). Working many hours, working a nonstandard schedule (such as night or weekend shifts), or experiencing a negative workplace atmosphere is associated with lower-quality parenting, fewer joint parent-child activities, poorer cognitive development, and increased behavior problems throughout childhood and adolescence (Li et al., 2014; Strazdins et al., 2006).

In contrast, part-time employment and flexible work schedules are associated with good child adjustment (Buehler & O'Brian, 2011; Youn, Leon, & Lee, 2012). By preventing role overload, these arrangements help parents meet children's needs.

### Support for Employed Parents and Their Families.

In dual-earner families, the father's willingness to share responsibilities is crucial. If he helps little or not at all, the mother carries a double load, at home and at work, leading to fatigue, distress, and little time and energy for children. Fortunately, compared to several decades ago, today's U.S. fathers are far more involved in child care (see page 204 in Chapter 6). But their increased participation has resulted in a growing number of fathers who also report role overload (Galinsky, Aumann, & Bond, 2009).

Employed parents need assistance from work settings and communities in their child-rearing roles. Part-time employment, flexible schedules, job sharing, on-site child care, and paid leave when children are ill help parents juggle the demands of work and child rearing (Butts, Casper, & Yang, 2013). Equal pay and employment opportunities for women are also important. Because these policies enhance financial status and morale, they improve the way mothers feel and behave when they arrive home at the end of the working day.

**Child Care for School-Age Children.** High-quality child care is vital for parents' peace of mind and children's well-being, even in middle childhood. An estimated 4.5 million 5- to 14-year-olds in the United States are **self-care children**, who regularly look after themselves for some period of time after school (Laughlin, 2013). Self-care increases with age and also with SES, perhaps because of the greater safety of higher-income neighborhoods. But when lower-SES parents lack alternatives to self-care, their children spend more hours on their own (Casper & Smith, 2002).

The implications of self-care for development depend on children's maturity and the way they spend their time. Among younger school-age children, those who spend more hours alone have more adjustment difficulties (Vandell & Posner, 1999). As

High-quality after-school programs with enrichment activities yield academic and social benefits, especially for low-SES children.

children become old enough to look after themselves, those whose parents engage in authoritative child rearing, monitor their activities through telephone calls, and assign regular after-school chores appear responsible and well-adjusted (Coley, Morris, & Hernandez, 2004; Vandell et al., 2006). In contrast, children left to their own devices are more likely to bend to peer pressures and engage in antisocial behavior.

Throughout middle childhood, attending after-school programs with well-trained and supportive staffs, generous adult-child ratios, and skill-building activities is linked to good school performance and emotional and social adjustment (Durlak, Weissberg, & Pachan, 2010; Kantaoka & Vandell, 2013). Low-SES children who participate in “after-care” programs offering academic assistance and enrichment activities (scouting, music and art lessons, clubs) show special benefits. They exceed their self-care counterparts in classroom work habits, academic achievement, and prosocial behavior and display fewer behavior problems (Lauer et al., 2006; Vandell et al., 2006).

Yet good after-care is in especially short supply in low-income neighborhoods (Greenberg, 2013). A special need exists for well-planned programs in these areas—ones that provide safe environments, warm relationships with adults, and enjoyable, goal-oriented activities.

## Ask yourself

**CONNECT** How does each level in Bronfenbrenner's ecological systems theory—microsystem, mesosystem, exosystem, and macrosystem—contribute to effects of parents' employment on children's development?

**APPLY** Steve and Marissa are in the midst of an acrimonious divorce. Their 9-year-old son Dennis has become hostile and defiant. How can Steve and Marissa help Dennis adjust?

**REFLECT** What after-school child-care arrangements did you experience in elementary school? How do you think they influenced your development?

## Some Common Problems of Development

- 10.11** Cite common fears and anxieties in middle childhood.
- 10.12** Discuss factors related to child sexual abuse, its consequences for children's development, and its prevention and treatment.
- 10.13** Cite factors that foster resilience in middle childhood.

We have considered a variety of stressful experiences that place children at risk for future problems. Next, we address two more areas of concern: school-age children's fears and anxieties and the consequences of child sexual abuse. Finally, we sum up factors that help children cope effectively with stress.

### Fears and Anxieties

Although fears of the dark, thunder and lightning, and supernatural beings persist into middle childhood, older children's anxieties are also directed toward new concerns. As children begin to understand the realities of the wider world, the possibility of personal harm (being robbed, stabbed, or shot) and media events (war and disasters) often trouble them. Other common worries include academic failure, physical injuries, separation from parents, parents' health, the possibility of dying, and peer rejection (Muris & Field, 2011; Weems & Costa, 2005).

As long as fears are not too intense, most children handle them constructively, using the more sophisticated emotional self-regulation strategies that develop in middle childhood. Consequently, overall number of fears declines with age, especially for girls, who express more fears than boys throughout childhood and adolescence (Gullone, 2000; Muris & Field, 2011). But about 5 percent of school-age children develop an intense, unmanageable fear called a **phobia**. Children with inhibited temperaments are at high risk, displaying phobias five to six times as often as other children (Ollendick, King, & Muris, 2002).

Some children with phobias and other anxieties develop *school refusal*—severe apprehension about attending school, often accompanied by physical complaints such as dizziness, nausea, stomachaches, and vomiting (Wimmer, 2013). About one-third of children with school refusal are 5- to 7-year-olds for whom the real fear is maternal separation (Elliott, 1999). Family therapy helps these children, whose difficulty can often be traced to parental overprotection.

Most cases of school refusal appear around age 11 to 13, in children who usually find a particular aspect of school frightening—an overcritical teacher, a school bully, or too much parental pressure to achieve. A change in school environment or parenting practices may be needed. Firm insistence that the child return to school, along with training in how to manage anxiety and cope with difficult situations, is also helpful (Kearney, Spear, & Mihalas, 2014).

Severe childhood anxieties may arise from harsh living conditions. In inner-city ghettos and in war-torn areas of the world, large numbers of children live in the midst of constant danger, chaos, and deprivation. As the Cultural Influences box on the

following page reveals, they are at risk for long-term emotional distress and behavior problems. Finally, as we saw in our discussion of child abuse in Chapter 8, too often violence and other destructive acts become part of adult–child relationships. During middle childhood, child sexual abuse increases.

### Child Sexual Abuse

Until recently, child sexual abuse was considered rare, and adults often dismissed children's claims of abuse. In the 1970s, efforts by professionals and media attention led to recognition of child sexual abuse as a serious and widespread problem. About 61,000 cases in the United States were confirmed in the most recently reported year (U.S. Department of Health and Human Services, 2015c).

**Characteristics of Abusers and Victims.** Sexual abuse is committed against children of both sexes, but more often against girls. Most cases are reported in middle childhood, but for some victims, abuse begins early in life and continues for many years (Collin-Vézina, Daigneault, & Hébert, 2013).

In the vast majority of cases, the abuser is male, often a parent or someone the parent knows well—a father, stepfather, live-in boyfriend, uncle, or older brother (Olafson, 2011). If the abuser is a nonrelative, the person is usually someone the child has come to know and trust, such as a teacher, caregiver, clergy member, or family friend (Sullivan et al., 2011). The Internet and mobile phones have become avenues through which some perpetrators commit sexual abuse—for example, by exposing children and adolescents to pornography and online sexual advances as a way of “grooming” them for sexual acts offline (Kloess, Beech, & Harkins, 2014).

Abusers make the child comply in a variety of distasteful ways, including deception, bribery, verbal intimidation, and physical force. You may wonder how any adult—especially a parent or close relative—could violate a child sexually. Many offenders deny their own responsibility, blaming the abuse on the willing participation of a seductive youngster. Yet children are not capable of making a deliberate, informed decision to enter into a sexual relationship! Even older children and adolescents are not free to say yes or no. Rather, the responsibility lies with abusers, who tend to have characteristics that predispose them toward sexual exploitation of children. They have great difficulty controlling their impulses and may suffer from psychological disorders, including alcohol and drug abuse. Often they pick out children who are unlikely to defend themselves or to be believed—those who are physically weak, emotionally deprived, socially isolated, or affected by disabilities (Collin-Vézina, Daigneault, & Hébert, 2013).

Reported cases of child sexual abuse are linked to poverty, marital instability, and resulting weakening of family ties. Children who live in homes with a constantly changing cast of characters—repeated marriages, separations, and new partners—are especially vulnerable (Murray, Nguyen, & Cohen, 2014). But children in economically advantaged, stable homes are also victims, although their abuse is more likely to escape detection.

## Cultural Influences

### Impact of Ethnic and Political Violence on Children

Around the world, many children live with armed conflict, terrorism, and other acts of violence stemming from ethnic and political tensions. Some children participate in fighting, either because they are forced or because they want to please adults. Others are kidnapped, assaulted, and tortured. Child bystanders often come under direct fire and may be killed or physically maimed. And many watch in horror as family members, friends, and neighbors flee, are wounded, or die. An estimated 25 million children live in conflict-ridden, poor countries. In the past decade, wars have left 6 million physically disabled, 20 million homeless, and more than 1 million separated from their parents (Masten et al., 2015; UNICEF, 2011).

When war and social crises are temporary, most children can be comforted and do not show long-term emotional difficulties. But chronic danger requires children to make substantial adjustments that can seriously impair their psychological functioning.

The greater children's exposure to life-threatening experiences, the more likely they are to display post-traumatic stress symptoms—extreme fear and anxiety, terrifying intrusive memories, depression, irritability, anger, aggression, and a pessimistic view of the future (Dimitry, 2012; Eisenberg & Silver, 2011). These outcomes appear to be culturally universal, emerging among children in every war zone studied—from Bosnia, Rwanda, and the Sudan to the West Bank, Gaza, Iraq, Afghanistan, and Syria.

Parental affection and reassurance are the best protection against lasting problems. When parents offer security, discuss traumatic experiences sympathetically, and serve as role

models of calm emotional strength, most children can withstand even extreme war-related violence (Gewirtz, Forgatch, & Wieling, 2008). Children separated from their parents, who are at greatest risk for maladjustment, must rely on help from their communities.

Orphans in Eritrea who were placed in residential settings where they could form a close emotional tie with an adult showed less emotional stress five years later than orphans placed in impersonal settings (Wolff & Fesseha, 1999). Education and recreation programs are powerful safeguards, too, providing children with consistency in their lives along with teacher and peer supports.

With the September 11, 2001, terrorist attacks on the World Trade Center, some U.S. children experienced extreme wartime violence firsthand. Most children, however, learned about the attacks indirectly—from the media or from caregivers or peers. Both direct and indirect exposure triggered child and adolescent distress, but extended exposure—having a family member affected or repeatedly witnessing the attacks on TV—resulted in more severe symptoms (Agronick et al., 2007; Rosen & Cohen, 2010). During the following months, distress reactions declined, though more slowly for children with pre-existing adjustment problems.

Unlike many war-traumatized children in the developing world, students in New York's

A refugee camp volunteer teaches Syrian students in a makeshift school. Educational and recreational programs provide children with consistency in severely stressful environments, helping to protect them from lasting adjustment problems.

AP PHOTO/BILAL HUSSEIN

Public School 31, who watched from their classroom windows as the towers collapsed, received immediate intervention—a “trauma curriculum” in which they expressed their emotions through writing, drawing, and discussion and participated in experiences aimed at helping them manage stress and restore trust and tolerance. Evaluations of similar school-based interventions in war-torn regions reveal that they are highly effective in lessening children's and adolescents' post-traumatic stress symptoms (Peltonen & Punamäki, 2010; Qouta et al., 2012).

When wartime drains families and communities of resources, international organizations must step in and help children. The Children and War Foundation, [www.childrenandwar.org](http://www.childrenandwar.org), offers programs and manuals that train local personnel in how to promote children's adaptive coping. Efforts to preserve children's physical, psychological, and educational well-being may be the best way to stop transmission of violence to the next generation.

**Consequences.** The adjustment problems of child sexual abuse victims—including anxiety, depression, low self-esteem, mistrust of adults, and anger and hostility—are often severe and can persist for years after the abusive episodes. Younger children frequently react with sleep difficulties, loss of appetite, and generalized fearfulness. Adolescents may run away and show suicidal reactions, eating disorders (including weight gain and obesity), substance abuse, and delinquency. At all ages,

persistent abuse accompanied by force, violence, and a close relationship to the perpetrator (incest) has a more severe impact. And sexual abuse, like physical abuse, is associated with central nervous system damage (Gaskill & Perry, 2012).

Sexually abused children frequently display precocious sexual knowledge and behavior. In adolescence, abused young people often become promiscuous, and as adults, they show increased arrest rates for sex crimes (mostly against children)

and prostitution. Furthermore, women who were sexually abused are likely to choose partners who abuse them and their children. As mothers, they often engage in irresponsible and coercive parenting, including child abuse and neglect (Collin-Vézina, Daigneault, & Hébert, 2013; Trickett, Noll, & Putnam, 2011). In these ways, the harmful impact of sexual abuse is transmitted to the next generation.

**Prevention and Treatment.** Because sexual abuse typically appears in the midst of other serious family problems, specialized trauma-focused therapy with both children and parents is usually needed (Saunders, 2012). The best way to reduce the suffering of victims is to prevent sexual abuse from continuing. Today, courts are prosecuting abusers more vigorously and taking children's testimony more seriously (see the Social Issues: Health box on the following page).

Educational programs that teach children to recognize inappropriate sexual advances and identify sources of help reduce the risk of abuse (Finkelhor, 2009). Yet because of controversies over educating children about sexual abuse, few schools offer these interventions. New Zealand is the only country with a national, school-based prevention program targeting sexual abuse. In *Keeping Ourselves Safe*, children and adolescents learn that abusers are rarely strangers. Parent involvement ensures that home and school collaborate in teaching children self-protection skills. Evaluations reveal that virtually all New Zealand parents and children support the program and that it has helped many children avoid or report abuse (Sanders, 2006).

## Fostering Resilience in Middle Childhood

Throughout middle childhood—and other periods of development—children encounter challenging and sometimes threatening situations that require them to cope with psychological stress. In this and the previous chapter, we have considered such topics as chronic illness, learning disabilities, achievement expectations, divorce, harsh living conditions and wartime trauma, and sexual abuse. Each taxes children's coping resources, creating serious risks for development.

Nevertheless, only a modest relationship exists between stressful life experiences and psychological disturbance in childhood (Masten, 2014). In our earlier discussions of poverty, troubled family lives, and birth complications, we noted that some children manage to surmount their negative impact. The same is true for school difficulties, family transitions, the experience of war, and child maltreatment. Recall from Chapter 1 that four broad factors protect against maladjustment: (1) the child's personal characteristics, including an easygoing temperament and a mastery-oriented approach to new situations; (2) a warm parental relationship; (3) an adult outside the immediate family who offers a support system; and (4) community resources, such as good schools, social services, and youth organizations and recreation centers.

Often just one or a few of these ingredients account for why one child is resilient and another is not. Usually, however,

personal and environmental factors are interconnected: Each resource favoring resilience strengthens others. For example, safe, stable neighborhoods with family-friendly community services reduce parents' daily hassles and stress, thereby promoting good parenting (Chen, Howard, & Brooks-Gunn, 2011). In contrast, unfavorable home, school, and neighborhood experiences increase the chances that children will act in ways that expose them to further hardship. And when negative conditions pile up, such as marital discord, poverty, crowded living conditions, school and neighborhood violence, and abuse and neglect, the rate of maladjustment multiplies (Masten & Cicchetti, 2010).

Several highly effective school-based social and emotional learning programs promote children's resilience by increasing academic motivation, social competence, and supportive relationships (Durlak et al., 2011). Among these is the 4Rs (Reading, Writing, Respect, and Resolution) Program, which provides elementary school students with weekly lessons in emotional and social understanding and skills. Topics include managing anger, responding with empathy, being assertive, resolving social conflicts, and standing up against prejudice and bullying. High-quality children's literature, selected for relevance to program themes, complements each lesson. Discussion, writing, and role-playing of the stories deepen students' understanding.

An evaluation of 4Rs in New York City public schools revealed that teachers implementing the intervention used more supportive instructional techniques, including making concepts relevant to students' everyday lives and providing feedback that acknowledges effort. And relative to controls, children who participated in 4Rs became less depressed, less aggressive, more attentive, and more socially competent (Aber et al., 2011). In unsafe neighborhoods, 4Rs transforms schools into places of safety and mutual respect, where learning can occur.

Programs like 4Rs recognize that *resilience* is not a pre-existing attribute but rather a capacity that develops, enabling children to use internal and external resources to cope with adversity (Luthar, Crossman, & Small, 2015). Throughout our discussion, we have seen how families, schools, communities, and society as a whole can enhance or undermine school-age children's developing sense of competence. As the next two chapters will reveal, young people whose childhood experiences helped them learn to control impulses, overcome obstacles, strive for self-direction, and respond considerately and sympathetically to others meet the challenges of the next period—adolescence—quite well.

## Ask yourself

**CONNECT** Explain how factors that promote resilience contribute to favorable adjustment following divorce.

**APPLY** Claire told her 6-year-old daughter never to talk to or take candy from strangers. Why is Claire's warning unlikely to protect her daughter from sexual abuse?

**REFLECT** Describe a challenging time during your childhood. What aspects of the experience increased stress? What resources helped you cope with adversity?

## Social Issues: Health

### Children's Eyewitness Testimony

Increasingly, children are being called on to testify in court cases involving child abuse and neglect, child custody, and similar matters. The experience can be traumatic, requiring children to report on highly stressful events and sometimes to speak against a parent or other relative to whom they feel loyal. In some family disputes, they may fear punishment for telling the truth. In addition, child witnesses are faced with an unfamiliar situation—at the very least an interview in the judge's chambers and at most an open courtroom with judge, jury, spectators, and the possibility of unsympathetic cross-examination. Not surprisingly, these conditions can compromise the accuracy of children's recall.

#### Age Differences

As a result of societal reactions to rising rates of child abuse and the difficulty of prosecuting perpetrators, age requirements for child testimony have been relaxed in the United States (Klemfuss & Ceci, 2012). Children as young as age 3 frequently serve as witnesses.

Compared with preschoolers, school-age children are better at giving accurate, detailed narrative accounts of past experiences and correctly inferring others' motives and intentions. Older children are also more resistant to misleading questions that attorneys may ask when probing for more information or, in cross-examination, trying to influence the child's response (Hobbs & Goodman, 2014).

Nevertheless, when properly questioned, even 3-year-olds can recall recent events accurately (Peterson & Rideout, 1998). And in the face of biased interviewing, adolescents and adults often form elaborate, false memories of events (Ceci et al., 2007).

#### Suggestibility

Court testimony often involves repeated questioning—a procedure that, by itself, negatively affects children's response consistency and accuracy (Krähenbühl, Blades, & Eiser, 2009). When adults lead child witnesses by suggesting incorrect "facts," interrupt their denials,

reinforce them for giving desired answers, ask complex and confusing questions, or use a confrontational style, they further increase the likelihood of incorrect reporting (Zajac, O'Neill, & Hayne, 2012).

By the time children appear in court, weeks, months, or even years have passed since the target events. When a long delay is combined with biased interviewing and with stereotyping of the accused ("He's in jail because he's been bad"), children can easily be misled into giving false information (Quas et al., 2007). The more distinctive, emotional, and personally relevant an event is, the more likely children are to recall it accurately over time, even after exposure to misleading suggestions (Goodman et al., 2014).

In many sexual abuse cases, anatomically correct dolls or body diagrams are used to prompt children's recall. Although these methods may help older children provide more detail, they increase the suggestibility of preschoolers, who may then report physical and sexual contact that never happened (Poole & Bruck, 2012).

#### Interventions

Adults must prepare child witnesses so they understand the courtroom process and know what to expect. In some places, "court schools" take children through the setting and give them an opportunity to role-play court activities. Practice interviews—in which children learn to provide the most accurate, detailed information possible and to admit

School-age eyewitnesses are better able than preschoolers to give accurate, detailed descriptions and correctly infer others' motives and intentions. This juvenile court judge can promote accurate recall by using a warm, supportive tone and avoiding leading questions.

not knowing rather than agreeing or guessing—are helpful (Zajac, O'Neill, & Hayne, 2012).

At the same time, legal professionals must use interviewing procedures that increase children's accurate reporting. Unbiased, open-ended questions that prompt children to disclose details—"Tell me what happened" or "You said there was a man; tell me about the man"—reduce suggestibility (Goodman et al., 2014; Steele, 2012). Also, a warm, supportive interview tone fosters accurate recall, perhaps by easing children's anxiety so they feel freer to disagree with an interviewer's false suggestions (Ceci, Bruck, & Battin, 2000).

If children are likely to experience emotional trauma or later punishment (as in a family dispute), courtroom procedures are sometimes adapted to protect them. For example, children can testify over closed-circuit TV so they do not have to face an abuser. When it is not wise for a child to participate directly, impartial expert witnesses can provide testimony that reports on the child's psychological condition and includes important elements of the child's story.

## Summary / chapter 10

### Erikson's Theory: Industry versus Inferiority (p. 336)

#### 10.1 What personality changes take place during Erikson's stage of industry versus inferiority?

- Children who successfully resolve Erikson's psychological conflict of **industry versus inferiority** develop a positive but realistic self-concept, pride in their accomplishments, a sense of moral responsibility, and cooperative participation with agemates.

ECO IMAGES/GETTY IMAGES

### Self-Understanding (p. 336)

#### 10.2 Describe school-age children's self-concept and self-esteem, and discuss factors that affect their achievement-related attributions.

- As school-age children gain in perspective-taking skills, their self-concepts increasingly include competencies, personality traits (both positive and negative), and **social comparisons**. Although parental support remains vital, children increasingly look to more people beyond the family for information about themselves.
- Self-esteem differentiates further and becomes hierarchically organized and more realistic. Cultural forces, gender-stereotyped expectations, and child-rearing practices contribute to variations in self-esteem. Authoritative parenting is linked to favorable self-esteem.
- Children who hold **mastery-oriented attributions** believe ability can be improved by trying hard and attribute failure to controllable factors, such as insufficient effort. In contrast, children who receive negative feedback about their ability are likely to develop **learned helplessness**, attributing success to external factors, such as luck, and failure to low ability.
- Process praise**, which emphasizes behavior and effort, encourages mastery-oriented attributions, whereas **person praise**, which focuses on fixed abilities, is linked to learned helplessness. Cultural valuing of effort also promotes a mastery-oriented approach.

### Emotional Development (p. 341)

#### 10.3 Cite changes in self-conscious emotions, emotional understanding, and emotional self-regulation in middle childhood.

- Self-conscious emotions of pride and guilt become clearly governed by personal responsibility. Intense shame is particularly destructive, yielding both internalizing and externalizing problems.
- School-age children develop an appreciation of mixed emotions, which enables them to reconcile contradictory cues in interpreting another's feelings. Empathy increases and includes sensitivity to both people's immediate distress and their general life condition.
- By age 10, most children shift adaptively between **problem-centered** and **emotion-centered coping** to regulate emotion. Children who acquire a sense of emotional self-efficacy are upbeat, empathic, and prosocial.

### Moral Development (p. 342)

#### 10.4 Describe changes in moral understanding during middle childhood, including children's understanding of diversity and inequality.

- By middle childhood, children have internalized rules for good conduct. They construct a flexible appreciation of moral rules based on intentions and context and develop a better understanding of personal choice and individual rights.
- School-age children absorb prevailing societal attitudes about race and ethnicity. With age, they pay more attention to inner traits, although implicit racial bias may persist. Children most likely to hold biases are those who believe that personality traits are fixed, who have inflated self-esteem, and who live in a social world that highlights group differences. Long-term intergroup contact is most effective at reducing prejudice.

© JIM WEST/ALAMY

### Peer Relations (p. 345)

#### 10.5 How do peer sociability and friendship change in middle childhood?

- Peer interaction becomes more prosocial, and physical aggression declines. By the end of middle childhood, children organize into **peer groups**.

© BJARKI REYR MIR/ALAMY

- Friendships develop into mutual relationships based on trust. Children tend to select friends similar to themselves in multiple ways.

#### 10.6 Describe major categories of peer acceptance and ways to help rejected children.

- On measures of **peer acceptance**, **popular children** are well-liked by many agemates; **rejected children** are strongly disliked; **controversial children** are both liked and disliked; **neglected children** arouse little reaction, positive or negative; and *average children* receive average numbers of positive and negative votes.
- Popular-prosocial children** combine academic and social competence, while **popular-antisocial children** are aggressive but admired. **Rejected-aggressive children** are especially high in conflict and hostility; in contrast, **rejected-withdrawn children** are passive, socially awkward, and frequent targets of **peer victimization**.
- Coaching in social skills, academic tutoring, and training in perspective taking and social problem solving can help rejected children gain in social competence and peer acceptance. Intervening to improve the quality of parent-child interaction is often necessary.

## Gender Typing (p. 350)

### 10.7 What changes in gender-stereotyped beliefs and gender identity occur during middle childhood?

- School-age children extend their awareness of gender stereotypes to personality traits and academic subjects. But they also broaden their view of what males and females can do.
- Boys strengthen their identification with masculine traits, whereas girls more often experiment with “other-gender” activities. Gender identity includes self-evaluations of gender typicality, contentedness, and felt pressure to conform to gender roles—each of which affects adjustment.

## Family Influences (p. 351)

### 10.8 How do parent–child communication and sibling relationships change in middle childhood?

- Despite declines in time spent with parents, **coregulation** allows parents to exercise general oversight over children, who increasingly make their own decisions.
- Sibling rivalry tends to increase with participation in a wider range of activities and more frequent parental comparisons. Only children do not differ from children with siblings in self-rated personality traits and are higher in self-esteem, school performance, and educational attainment.

### 10.9 What factors influence children’s adjustment to divorce and blended family arrangements?

- Marital breakup is often quite stressful for children. Individual differences are affected by parental psychological health, financial well-being, child characteristics (age, temperament, and sex), and social supports. Children with difficult temperaments are at greater risk for adjustment problems. Divorce is linked to early sexual activity, adolescent parenthood, and long-term relationship difficulties.

- The overriding factor in positive adjustment following divorce is effective parenting. Positive father–child relationships are protective, as are supports from extended-family members, teachers, siblings, and friends. Divorce mediation can foster parental conflict resolution in the period surrounding divorce. The success of joint custody depends on effective coparenting.

© BURGER/PHANIE/THE IMAGE WORKS

- In **blended**, or **reconstituted**, families, girls, older children, and children in father–stepmother families tend to have more adjustment problems. Stepparents who move into their roles gradually help children adjust.

### 10.10 How do maternal employment and life in dual-earner families affect school-age children?

- When employed mothers remain committed to parenting, children display higher self-esteem, less gender-stereotyped beliefs, better achievement, and fewer behavior problems. In dual-earner families, the father’s willingness to share responsibilities is a crucial factor. Workplace supports help parents in their child-rearing roles.
- Authoritative child rearing, parental monitoring, and regular after-school chores lead **self-care children** to be responsible and well-adjusted. Good “after-care” programs also aid school performance and emotional and social adjustment, especially for low-SES children.

## Some Common Problems of Development (p. 358)

### 10.11 Cite common fears and anxieties in middle childhood.

- School-age children’s fears include physical harm, media events, academic failure, parents’ health, the possibility of dying, and peer rejection. Children with inhibited temperaments are at higher risk of developing **phobias**. Harsh living conditions can also cause severe anxiety.

### 10.12 Discuss factors related to child sexual abuse, its consequences for children’s development, and its prevention and treatment.

- Child sexual abuse is typically committed by male family members, more often against girls than boys. Abusers have characteristics that predispose them toward sexual exploitation of children. Reported cases are strongly associated with poverty and marital instability. Abused children often have severe adjustment problems.
- Treatment for abused children typically requires long-term therapy with both children and parents. Educational programs that teach children to recognize inappropriate sexual advances and identify sources of help reduce the risk of sexual abuse.

### 10.13 Cite factors that foster resilience in middle childhood.

- Only a modest relationship exists between stressful life experiences and psychological disturbance in childhood. Children’s personal characteristics, a warm family life, authoritative parenting, and school, community, and societal resources predict resilience.

# milestones

## Development in Middle Childhood

### 6–8 YEARS

#### Physical

- Slow gains in height and weight continue. (294)
- Permanent teeth gradually replace primary teeth. (294)
- Legibility of writing increases. (300)
- Drawings become more organized and detailed and include some depth cues. (300)
- Games with rules and rough-and-tumble play become common. (301, 302)

PHOTO AND CO/PHOTODISC/GETTY IMAGES

#### Cognitive

- Thought becomes more logical, as shown by the ability to pass Piagetian conservation, class inclusion, and seriation problems. (304)

LAURA DWIGHT PHOTOGRAPHY

- Improves dramatically in speed of information processing. (308)
- Gains further in executive function, with marked improvements in inhibition, flexible shifting of attention, working memory capacity, and planning on multistep tasks. (308, 310)
- Uses memory strategies of rehearsal and then organization. (310)
- Views the mind as an active, constructive agent, capable of transforming information. (311)
- Awareness of memory strategies and of the impact of psychological factors, such as mental inferences, on performance improve. (311–312)
- Understands second-order false belief; capable of recursive thought. (312)
- Uses informal knowledge of number concepts and counting to master increasingly complex mathematical skills. (313)

#### Language

- Vocabulary increases rapidly throughout middle childhood, eventually reaching comprehension of 40,000 words. (321)
- Word definitions are concrete, referring to functions and appearance. (322)
- Transitions from emergent literacy to conventional reading. (313)

IMAGE SOURCE/ALAMY

- Language awareness develops. (321)
- Understands and uses increasingly subtle, indirect expressions of meaning, such as irony and sarcasm. (322)
- Narratives increase in organization, detail, and expressiveness. (322)

#### Emotional/Social

- Self-concept begins to include personality traits, competencies, and social comparisons. (336)
- Self-esteem differentiates, becomes hierarchically organized, and adjusts to a more realistic level. (337)
- Self-conscious emotions of pride and guilt are governed by personal responsibility. (341)
- Recognizes that individuals can experience more than one emotion at a time and that their expressions may not reflect their true feelings. (341–342)

LAURA DWIGHT PHOTOGRAPHY

- Reconciles contradictory facial and situational cues in understanding another's feelings. (342)
- Empathy increases. (342)
- Becomes more independent and trustworthy. (342–343)
- Constructs a flexible appreciation of moral rules, taking prosocial and antisocial intentions into account. (343)
- Physical aggression declines; verbal and relational aggression continue. (345–346)
- Resolves conflicts more effectively. (345–346)

### 9–11 YEARS

#### Physical

- Adolescent growth spurt begins two years earlier in girls than in boys. (294)
- Executes gross-motor skills of running, jumping, throwing, catching, kicking, batting, and dribbling more quickly and with better coordination. (299–300)

Note: Numbers in parentheses indicate the page or pages on which each milestone is discussed.

- Ability to represent depth in drawings expands. (300)
- Dominance hierarchies become more stable, especially among boys. (302)

## Cognitive

- Continues to master concrete operational tasks in a step-by-step fashion. (306)
- Spatial reasoning improves; readily draws and reads maps of large-scale spaces, grasps the notion of scale, and understands map symbols. (304–305)

- Continues to improve in speed of information processing. (308)
- Continues to gain in executive function. (308, 309)
- Uses memory strategies of rehearsal and organization more effectively. (310)
- Applies several memory strategies simultaneously; begins to use elaboration. (310–311)

- General knowledge base (semantic memory) grows larger and becomes better organized. (311)
- Theory of mind becomes more elaborate and refined. (311–312)
- Cognitive self-regulation improves. (312–313)

## Language

- Thinks about and uses words more precisely; word definitions emphasize synonyms and categorical relations. (322)
- Grasps multiple meanings of words, as reflected in comprehension of metaphors and humor. (322)
- Continues to master complex grammatical constructions. (322)

- Narratives lengthen, become more coherent, and include more evaluative comments. (322)

## Emotional/Social

- Self-esteem remains high but continues to become more realistic and nuanced. (337)
- Distinguishes ability, effort, and external factors (such as luck) in attributions for success and failure. (339)
- Empathic responding extends to general life conditions. (342)
- Shifts adaptively between problem-centered and emotion-centered strategies in regulating emotion. (342)
- Becomes more knowledgeable about socially approved ways to display negative emotion. (342)

- Clarifies and links moral rules and social conventions. (343)
- Convictions about matters of personal choice strengthen, and understanding of individual rights expands. (343–344)
- Explicit outgroup prejudice declines. (344–345)
- Friendships become more selective and are based on mutual trust. (346)
- Peer groups emerge. (346)

- Becomes aware of more gender stereotypes, including personality traits and achievement, but has a flexible appreciation of what males and females can do. (350)
- Gender identity expands to include self-evaluations of typicality, contentedness, and felt pressure to conform. (351)
- Sibling rivalry tends to increase. (352)

## Physical and Cognitive Development in Adolescence

The dramatic physical and cognitive changes of adolescence make it both an exhilarating and apprehensive period of development. Although their bodies are full-grown and sexually mature, these teenagers have many skills to acquire and hurdles to surmount before they are ready for full assumption of adult roles.

■ **SOCIAL ISSUES: EDUCATION** Media Multitasking Disrupts Learning

On Sabrina's eleventh birthday, her friend Joyce gave her a surprise party, but Sabrina seemed somber during the celebration. Although Sabrina and Joyce had been close friends since third grade, their relationship was faltering. Sabrina was a head taller and some 20 pounds heavier than most girls in her sixth-grade class. Her breasts were well-developed, her hips and thighs had broadened, and she had begun to menstruate. In contrast, Joyce still had the short, lean, flat-chested body of a school-age child.

Ducking into the bathroom while the other girls put candles on the cake, Sabrina frowned at her image in the mirror. "I'm so big and heavy," she whispered. At church youth group on Sunday evenings, Sabrina broke away from Joyce and joined the eighth-grade girls. Around them, she didn't feel so large and awkward.

Once a month, parents gathered at Sabrina's and Joyce's school to discuss child-rearing concerns. Sabrina's parents, Franca and Antonio, attended whenever they could. "How you know they are becoming teenagers is this," volunteered Antonio. "The bedroom door is closed, and they want to be alone. Also, they contradict and disagree. I tell Sabrina, 'You have to go to Aunt Gina's on Saturday for dinner with the family.' The next thing I know, she's arguing with me."

Sabrina has entered **adolescence**, the transition between childhood and adulthood.

In industrialized societies, the skills young people must master are so complex and the choices confronting them so diverse that adolescence is greatly extended. But around the world, the basic tasks of this period are much the same. Sabrina must accept her full-grown body, acquire adult ways of thinking, attain greater independence from her family, develop more mature ways of relating to peers of both sexes, and begin to construct an identity—a secure sense of who she is in terms of sexual, vocational, moral, ethnic, religious, and other life values and goals.

The beginning of adolescence is marked by **puberty**, a flood of biological events leading to an adult-sized body and sexual maturity. As Sabrina's reactions suggest, entry into adolescence can be an especially trying time for some young people. In this chapter, we trace the events of puberty and take up a variety of health concerns—physical exercise, nutrition, sexual activity, substance use and abuse, and other challenges that many teenagers encounter on the path to maturity.

Adolescence also brings with it vastly expanded powers of reasoning. Teenagers can grasp complex scientific and mathematical principles, grapple with social and political issues, and delve deeply into the meaning of a poem or story. The second part of this chapter traces these extraordinary changes from both Piaget's and the information-processing perspective. Next, we examine sex differences in mental abilities. Finally, we turn to the main setting in which adolescent thought takes shape: the school. ●

© DANIEL GRILL/TETRA IMAGES/CORBIS

## PHYSICAL DEVELOPMENT

### Conceptions of Adolescence

**11.1** How have conceptions of adolescence changed over the past century?

Why is Sabrina self-conscious, argumentative, and in retreat from family activities? Historically, theorists explained the impact of puberty on psychological development by resorting to extremes—either a biological or a social explanation. Today, researchers realize that biological and social forces jointly determine adolescent psychological change.

### The Biological Perspective

Ask several parents of young children what they expect their sons and daughters to be like as teenagers, and you will probably get answers like these: “Rebellious and irresponsible,” “Full of rages and tempers.” This widespread storm-and-stress view dates back to major early-twentieth-century theorists. The most influential, G. Stanley Hall (1904), who based his ideas on Darwin’s theory of evolution, described adolescence as a period so turbulent that it resembled the era in which humans evolved from savages into civilized beings. Similarly, in Freud’s psychosexual theory, sexual impulses reawaken in the *genital stage*, triggering psychological conflict and volatile behavior. As adolescents find intimate partners, inner forces gradually achieve a new, mature harmony, and the stage concludes with marriage, birth, and child rearing. In this way, young people fulfill their biological destiny: sexual reproduction and survival of the species.

### The Social Perspective

Contemporary research suggests that the storm-and-stress notion of adolescence is exaggerated. Certain problems, such as eating disorders, depression, suicide, and lawbreaking, do occur more often than earlier. But the overall rate of serious psychological disturbance rises only slightly from childhood to adolescence, reaching 15 to 20 percent (Merikangas et al., 2010). Though much greater than the adulthood rate (about 6 percent), emotional turbulence is not a routine feature of the teenage years.

The first researcher to point out the wide variability in adolescent adjustment was anthropologist Margaret Mead (1928). She returned from the Pacific islands of Samoa with a startling conclusion: Because of the culture’s relaxed social relationships and openness toward sexuality, adolescence “is perhaps the pleasantest time the Samoan girl (or boy) will ever know” (p. 308). In Mead’s alternative view, the social environment is entirely responsible for the range of teenage experiences, from erratic and agitated to calm and stress-free. Later researchers found that Samoan adolescence was not as untroubled as Mead

had assumed (Freeman, 1983). Still, she showed that to understand adolescent development, researchers must pay greater attention to social and cultural influences.

### A Balanced Point of View

Today we know that biological, psychological, and social forces combine to influence adolescent development (Hollenstein & Loughheed, 2013). Biological changes are universal—found in all primates and all cultures. These internal stresses and the social expectations accompanying them—that the young person give up childish ways, develop new interpersonal relationships, and take on greater responsibility—are likely to prompt moments of uncertainty, self-doubt, and disappointment in all teenagers. Adolescents’ prior and current experiences affect their success in surmounting these challenges.

At the same time, the length of adolescence and its demands and pressures vary substantially among cultures. Most tribal and village societies have only a brief intervening phase between childhood and full assumption of adult roles (Lancy, 2008). In industrialized nations, young people face prolonged dependence on parents and postponement of sexual gratification while they prepare for a productive work life. As a result, adolescence is greatly extended—so much so that researchers commonly divide it into three phases:

1. *Early adolescence* (11 to 14 years): This is a period of rapid pubertal change.
2. *Middle adolescence* (14 to 16 years): Pubertal changes are now nearly complete.
3. *Late adolescence* (16 to 18 years): The young person achieves full adult appearance and anticipates assumption of adult roles.

The more the social environment supports young people in achieving adult responsibilities, the better they adjust. For all the biological tensions and uncertainties about the future that teenagers feel, most negotiate this period successfully. With this in mind, let’s look closely at puberty, the dawning of adolescent development.

### Puberty: The Physical Transition to Adulthood

**11.2** Describe body growth, motor performance, and sexual maturation during puberty.

**11.3** What factors influence the timing of puberty?

**11.4** What changes in the brain take place during adolescence?

The changes of puberty are dramatic. Within a few years, the school-age child’s body transforms into that of a full-grown adult. Genetically influenced hormonal processes regulate pubertal growth. Girls, who have been advanced in physical maturity

since the prenatal period, reach puberty, on average, two years earlier than boys.

## Hormonal Changes

The complex hormonal changes that underlie puberty occur gradually and are under way in middle childhood. Secretions of *growth hormone (GH)* and *thyroxine* (see Chapter 7, page 219) increase, eventually leading to tremendous gains in body size and to attainment of skeletal maturity.

Sexual maturation is controlled by the sex hormones. Although we think of *estrogens* as female hormones and *androgens* as male hormones, both types are present in each sex but in different amounts. Sex hormones begin to rise long before physical changes are visible, typically between ages 6 and 8, when the adrenal glands on top of each kidney start to release increasing levels of *adrenal androgens*. By age 10, levels of adrenal androgens have increased tenfold, and some children experience their first feelings of sexual attraction (Best & Fortenberry, 2013).

Adrenal androgens influence girls' height spurt, and they stimulate growth of underarm and pubic hair. (Adrenal androgens have little visible impact on boys, whose physical characteristics are mainly influenced by androgen secretions from the testes.) Estrogens released by girls' maturing ovaries contribute to the height spurt by stimulating GH secretion, and they cause the breasts, uterus, and vagina to mature, the body to take on feminine proportions, and fat to accumulate. In addition, estrogens play a crucial role in regulating the menstrual cycle.

Boys' maturing testes release large quantities of the androgen *testosterone*, which leads to muscle growth, body and facial hair, and other male sex characteristics. Androgens (especially testosterone) exert a GH-enhancing effect, contributing greatly to gains in body size. The testes secrete small amounts of estrogen as well, which add to the growth spurt and lead many boys to experience temporary breast enlargement. In both sexes, estrogens in combination with androgens stimulate gains in bone density, which continue into early adulthood (Ambler, 2013; Cooper, Sayer, & Dennison, 2006).

As you can see, pubertal changes are of two broad types: (1) overall body growth and (2) maturation of sexual characteristics. We have seen that the hormones responsible for sexual maturity also affect body growth, making puberty the time of greatest sexual differentiation since prenatal life.

## Body Growth

The first outward sign of puberty is the rapid gain in height and weight known as the **growth spurt**. On average, it is under way for North American and Western European girls shortly after age 10, for boys around age 12½. Because estrogens trigger and then restrain GH secretion more readily than androgens, the typical girl is taller and heavier during early adolescence. By age 13½, however, she is surpassed by the typical boy, whose

Sex differences in pubertal growth are obvious among these 11-year-olds. Compared with the boys, the girls are taller and more mature-looking.

adolescent growth spurt has now started, whereas hers is almost finished (Ambler, 2013). Growth in body size is complete for most girls by age 16 and for boys by age 17½, when the epiphyses at the ends of the long bones close completely (see Chapter 7, page 217). Altogether, adolescents add 10 to 11 inches in height and 50 to 75 pounds—nearly 50 percent of adult body weight. Figure 11.1 on page 370 illustrates pubertal changes in general body growth.

**Body Proportions.** During puberty, the cephalocaudal growth trend of infancy and childhood reverses. The hands, legs, and feet accelerate first, followed by the torso, which accounts for most of the adolescent height gain. This pattern helps explain why early adolescents often appear awkward and out of proportion—long-legged, with giant feet and hands.

Large sex differences in body proportions also appear, caused by the action of sex hormones on the skeleton. Boys' shoulders broaden relative to the hips, whereas girls' hips broaden relative to the shoulders and waist. Of course, boys also end up larger than girls, and their legs are longer in relation to the rest of the body—mainly because boys have two extra years of preadolescent growth, when the legs are growing the fastest.

## Muscle–Fat Makeup and Other Internal Changes.

Around age 8, girls start to add fat on their arms, legs, and trunk, a trend that accelerates between ages 11 and 16. In contrast, arm and leg fat decreases in adolescent boys. Although both sexes gain in muscle, this increase is much greater in boys, who develop larger skeletal muscles, hearts, and lung capacity (Rogol, Roemmich, & Clark, 2002). Also, the number of red blood cells—and therefore the ability to carry oxygen from the lungs to the muscles—increases in boys but not in girls. Altogether, boys gain far more muscle strength than girls, a difference that contributes to boys' superior athletic performance during the teenage years (Greydanus, Omar, & Pratt, 2010).

**FIGURE 11.1** Body growth during adolescence. Because the pubertal growth spurt takes place earlier for girls than for boys, Mariel reached her adult body size earlier than Steven. Rapid pubertal growth is accompanied by large sex differences in body proportions.

## Motor Development and Physical Activity

Puberty brings steady improvements in gross motor performance, but the pattern of change differs for boys and girls. Girls' gains are slow and gradual, leveling off by age 14. In contrast, boys show a dramatic spurt in strength, speed, and endurance that continues through the teenage years. By midadolescence, few girls perform as well as the average boy in running speed, broad jump, or throwing distance. And practically no boys score as low as the average girl (Greydanus, Omar, & Pratt, 2010; Haywood & Getchell, 2014).

Among boys, athletic competence is strongly related to peer admiration and self-esteem. Some adolescents become so obsessed with physical prowess that they turn to performance-enhancing drugs. In recent large-scale studies, more than 9 percent of U.S. high school seniors, mostly boys, reported using creatine, an over-the-counter substance that enhances short-term muscle power but is associated with serious side effects, including muscle tissue disease, brain seizures, and heart irregularities. About 2 percent of seniors, again mostly boys, have taken anabolic steroids or a related substance, androstenedione—powerful

prescription medications that boost muscle mass and strength (Johnston et al., 2015). Teenagers usually obtain steroids illegally, ignoring side effects, which range from acne, excess body hair, and high blood pressure to mood swings, aggressive behavior, and damage to the liver, circulatory system, and reproductive organs (Denham, 2012). Coaches and health professionals should inform teenagers of the dangers of these performance-enhancing substances.

In 1972, the U.S. federal government required schools receiving public funds to provide equal opportunities for males and females in all educational programs, including athletics. Since then, high school girls' sports participation has increased, although it still falls far short of boys'. According to a recent survey of all 50 U.S. state high school athletic associations, 42 percent of sports participants are girls, 58 percent boys (National Federation of State High School Associations, 2016). In Chapter 9, we saw that girls get less encouragement and recognition for athletic achievement, a pattern that starts early and persists into the teenage years (see page 301).

Furthermore, when researchers followed a large, representative sample of U.S. youths from ages 9 to 17, daily free-time physical activity declined with age, more so for girls than boys.

© GREG SORBER/ZUMA PRESS/CORBIS

High school students run in their school's cross country invitational. Endurance sports that do not require an organized team or special facilities are especially likely to be sustained into adulthood.

And at every age, only a minority of participants engaged in regular exercise outside of school hours (see Figure 11.2) (Wall et al., 2011). In high school, just 55 percent of U.S. boys and 48 percent of girls receive any physical education, with just 30 percent of all students experiencing a daily physical education class (Kann et al., 2016).

**FIGURE 11.2** Decline in free-time physical activity from ages 9 to 17 among U.S. boys and girls. In a longitudinal-sequential investigation of a U.S. nationally representative sample of over 1,600 youths followed from ages 9 to 17, the percentage engaging in at least seven sessions of free-time daily exercise (sports, free-time daily exercise, playing actively with friends) in the previous week declined from 38 to 27 percent among boys and 31 to 16 percent among girls. Throughout adolescence, boys exceeded girls in regular daily exercise. (Based on Wall et al., 2011.)

Besides improving motor performance, sports and exercise influence cognitive and social development. Interscholastic and intramural athletics provide important lessons in teamwork, problem solving, assertiveness, and competition. And regular, sustained physical activity—which required physical education can ensure—is associated with lasting physical and mental health benefits (Brand et al., 2010).

Adolescents vary in their enjoyment of sports and exercise, leading to differences in continued involvement. In one study, participating in team or individual sports at age 14 at least once a week for girls and twice a week for boys predicted high physical activity rates at age 31. Endurance sports, such as running and cycling—activities that do not require an organized team or special facilities—were especially likely to continue into adulthood (Tammelin et al., 2003). And adolescent exertion during exercise, defined as sweating and breathing heavily, is one of the best predictors of adult physical exercise, perhaps because it fosters high *physical self-efficacy*—belief in one's ability to sustain an exercise program (Motl et al., 2002; Telama et al., 2005).

## Sexual Maturation

Accompanying rapid body growth are changes in physical features related to sexual functioning. Some, called **primary sexual characteristics**, involve the reproductive organs (ovaries, uterus, and vagina in females; penis, scrotum, and testes in males). Others, called **secondary sexual characteristics**, are visible on the outside of the body and serve as additional signs of sexual maturity (for example, breast development in females and the appearance of underarm and pubic hair in both sexes). As Table 11.1 on page 372 shows, these characteristics develop in a fairly standard sequence, although the ages at which each begins and is completed vary greatly. Typically, pubertal development takes about 4 years, but some adolescents complete it in 2 years, whereas others take 5 to 6 years.

**Sexual Maturation in Girls.** Female puberty usually begins with the budding of the breasts and the growth spurt. **Menarche**, or first menstruation, typically occurs around age 12½ for North American girls, 13 for Western Europeans. But the age range is wide, from 10½ to 15½ years. Following menarche, breast and pubic hair growth are completed, and underarm hair appears.

Notice in Table 11.1 that nature delays sexual maturity until the girl's body is large enough for childbearing; menarche takes place after the peak of the height spurt. As an extra measure of security, for 12 to 18 months following menarche, the menstrual cycle often occurs without the release of an ovum from the ovaries (Fuqua & Rogol, 2013). But this temporary period of sterility does not occur in all girls, and it does not provide reliable protection against pregnancy.

**Sexual Maturation in Boys.** The first sign of puberty in boys is the enlargement of the testes (glands that manufacture sperm), accompanied by changes in the texture and color of the scrotum. Pubic hair emerges soon after, about the same time the penis begins to enlarge (Fuqua & Rogol, 2013).

**TABLE 11.1**  
**Pubertal Development in North American Girls and Boys**

GIRLS	AVERAGE AGE		BOYS	AVERAGE AGE	
	ATTAINED	AGE RANGE		ATTAINED	AGE RANGE
Breasts begin to “bud”	10	8–13	Testes begin to enlarge	11.5	9.5–13.5
Height spurt begins	10	8–13	Pubic hair appears	12	10–15
Pubic hair appears	10.5	8–14	Penis begins to enlarge	12	10.5–14.5
Peak strength spurt	11.6	9.5–14	Height spurt begins	12.5	10.5–16
Peak height spurt	11.7	10–13.5	Spermarche (first ejaculation) occurs	13.5	12–16
Menarche (first menstruation) occurs	12.5	10.5–15.5	Peak height spurt	14	12.5–15.5
Peak weight spurt	12.7	10–14	Peak weight spurt	14	12.5–15.5
Adult stature reached	13	10–16	Facial hair begins to grow	14	12.5–15.5
Pubic hair growth completed	14.5	14–15	Voice begins to deepen	14	12.5–15.5
Breast growth completed	15	10–17	Penis and testes growth completed	14.5	12.5–16
			Peak strength spurt	15.3	13–17
			Adult stature reached	15.5	13.5–17.5
			Pubic hair growth completed	15.5	14–17

As Table 11.1 reveals, the growth spurt occurs much later in the sequence of pubertal events for boys than for girls. When it reaches its peak around age 14, enlargement of the testes and penis is nearly complete, and underarm hair appears. So do facial and body hair, which increase gradually for several years. Another landmark of male physical maturity is the deepening of the voice as the larynx enlarges and the vocal cords lengthen. (Girls’ voices also deepen slightly.) Voice change usually takes place at the peak of the male growth spurt and often is not complete until puberty is over (Archibald, Graber, & Brooks-Gunn, 2006).

While the penis is growing, the prostate gland and seminal vesicles (which together produce semen, the fluid containing sperm) enlarge. Then, around age 13½, **spermarche**, or first ejaculation, occurs (Rogol, Roemmich, & Clark, 2002). For a while, the semen contains few living sperm. So, like girls, boys have an initial period of reduced fertility.

## Individual Differences in Pubertal Growth

Heredity contributes substantially to the timing of pubertal changes. Identical twins are more similar than fraternal twins in attainment of most pubertal milestones (Eaves et al., 2004; Jahanfar, Lye, & Krishnarajah, 2013).

Nutrition and exercise also make a difference. In females, a sharp rise in body weight and fat may hasten sexual maturation. Fat cells release a protein called *leptin*, which is believed to signal the brain that the girl’s energy stores are sufficient for puberty—a likely reason that breast and pubic hair growth and menarche occur earlier for heavier and, especially, obese girls. In contrast, girls who begin rigorous athletic training at an early age or who eat very little (both of which reduce the percentage of body fat) usually experience later puberty (Kaplowitz, 2008; Rubin et al., 2009). Few studies, however, report a link between body fat and puberty in boys.

Variations in pubertal growth also exist among regions of the world and among SES and ethnic groups. Physical health plays a major role. In poverty-stricken regions where malnutrition and infectious disease are common, menarche is greatly delayed, occurring as late as age 14 in parts of Africa and Asia. Within developing countries, girls from higher-income families reach menarche 6 to 18 months earlier than those living in economically disadvantaged homes (Parent et al., 2003; Zhu et al., 2016).

But in industrialized nations where food is abundant, the joint roles of heredity and environment in pubertal growth are apparent. For example, breast and pubic hair growth begin, on average, around age 9 in African-American girls—a year earlier than in European-American girls. And African-American

girls reach menarche about six months earlier, around age 12 (Ramnitz & Lodish, 2013). Although widespread overweight and obesity in the black population contribute, a genetically influenced faster rate of physical maturation is also involved. Black girls usually reach menarche before white girls of the same age and body weight (Reagan et al., 2012).

Early family experiences may also affect pubertal timing. One theory suggests that humans have evolved to be sensitive to the emotional quality of their childhood environments. When children's safety and security are at risk, it is adaptive for them to reproduce early. Research indicates that girls and (less consistently) boys with a history of family conflict, harsh parenting, parental separation, or single mothers tend to reach puberty early. In contrast, those with warm, stable family ties reach puberty relatively late (Belsky et al., 2007a; Boynton-Jarrett et al., 2013; Ellis & Essex, 2007; Ellis et al., 2011; Webster et al., 2014). For girls, two longitudinal studies confirm this chain of influence from adverse childhood family environments to earlier pubertal timing to increased adolescent sexual risk taking (Belsky et al., 2010; James et al., 2012).

In the research we have considered, threats to emotional health accelerate puberty, whereas threats to physical health delay it. A **secular trend**, or generational change, in pubertal timing lends added support to the role of physical well-being in pubertal development. In industrialized nations, age of menarche declined steadily—by about 3 to 4 months per decade—from 1900 to 1970, a period in which nutrition, health care, sanitation, and control of infectious disease improved greatly. Boys, too, have reached puberty earlier in recent decades (Herman-Giddens et al., 2012). And as developing nations make socioeconomic progress, they also show secular gains.

In most industrialized nations, the trend toward earlier menarche has stopped or undergone a slight reversal (Sørensen et al., 2012). But in the United States and a few European countries, soaring rates of overweight and obesity are responsible for a modest, continuing trend toward earlier menarche (Gonzalez-Feliciano, Maisonet, & Marcus, 2013; Henk et al., 2013). A worrisome consequence is that girls who reach sexual maturity at age 10 or 11 will feel pressure to act much older than they are. As we will see shortly, early-maturing girls are at risk for unfavorable peer involvements, including sexual activity.

## Brain Development

The physical transformations of adolescence include major changes in the brain. Brain-imaging research reveals continued pruning of unused synapses in the cerebral cortex, especially the prefrontal cortex. Growth and myelination of stimulated neural fibers accelerate, further strengthening connections among various brain regions. In particular, linkages between the prefrontal cortex and other areas in the cerebral cortex and the inner brain (including the amygdala and hippocampus) expand and attain rapid communication (Blakemore, 2012; Chavarria et al., 2014; Goddings & Giedd, 2014). Consequently, adolescents gain in diverse cognitive skills, including executive function, reasoning, problem solving, and decision making.

But these advances in cognitive control occur gradually over the teenage years. fMRI evidence reveals that adolescents recruit the prefrontal cortex's network of connections with other brain areas less effectively than adults do. Because the *prefrontal cognitive-control network* still requires fine-tuning, teenagers' performance on tasks requiring inhibition, planning, and delay of gratification (rejecting a smaller immediate reward in favor of a larger, later reward) is not yet fully mature (Luna, Padmanabhan, & Geier, 2014; Smith, Xiao, & Bechara, 2012; Steinberg et al., 2009).

Adding to these executive function and self-regulation difficulties are changes in the brain's *emotional/social network*. As humans and other mammals become sexually mature, neurons become more responsive to excitatory neurotransmitters. As a result, adolescents react more strongly to stressful events and experience pleasurable stimuli more intensely. Changes in the emotional/social network also increase adolescents' sensitivity to social stimuli, making them highly reactive to peer influence and evaluation (Somerville, 2013).

Because the cognitive-control network is not yet functioning optimally, most teenagers find it especially difficult to manage these powerful feelings and impulses (Albert, Chein, & Steinberg, 2013; Casey, Jones, & Somerville, 2011). This imbalance contributes to teenagers' unchecked drive for novel experiences, including drug taking, reckless driving, unprotected sex, and delinquent activity. In a longitudinal study of a large, representative sample of U.S. youths, researchers tracked changes in self-reported impulsivity and sensation seeking between ages 12 and 24 (Harden & Tucker-Drob, 2011). As Figure 11.3 shows, impulsivity declined steadily with age—evidence of gradual improvement

**FIGURE 11.3** Development of impulsivity and sensation seeking from 12 to 24 years. In this longitudinal study of a large, representative sample of 7,600 U.S. youths, impulsivity declined steadily, while sensation seeking increased in early adolescence and then diminished more gradually. Findings confirm the challenge that the emotional/social network poses to the cognitive-control network. (From K. P. Harden and E. M. Tucker-Drob, 2011, "Individual Differences in the Development of Sensation Seeking and Impulsivity During Adolescence: Further Evidence of a Dual Systems Model," *Developmental Psychology*, 47, p. 742. Copyright © 2011 by the American Psychological Association. Adapted with permission of the American Psychological Association.)

© JANINE WIEDEL PHOTO LIBRARY/ALAMY

Changes in the brain's emotional/social network outpace development of the prefrontal cognitive-control network, contributing to teenagers' drive for novel experiences, receptiveness to peer influence, and risk-taking behavior.

of the cognitive-control network. But sensation seeking increased from 12 to 16, followed by a more gradual decline through age 24, reflecting the challenge posed by the emotional/social network.

In sum, changes in the adolescent brain's emotional/social network outpace development of the cognitive-control network. Only over time are young people able to effectively manage their emotions and reward-seeking behavior. Of course, wide individual differences exist in the extent to which teenagers manifest this rise in risk taking in the form of careless, dangerous acts. Temperament, parenting, SES, and neighborhood resources, which are linked to encouragement and opportunities to take risks, make a difference (Hollenstein & Loughheed, 2013). Nevertheless, transformations in the adolescent brain enhance our understanding of both the cognitive advances and the worrisome behaviors of this period, along with teenagers' need for adult patience, oversight, and guidance.

## Changing States of Arousal

At puberty, revisions occur in the way the brain regulates the timing of sleep, perhaps because of increased neural sensitivity to evening light. As a result, adolescents go to bed much later than they did as children. Yet they need almost as much sleep as they did in middle childhood—about nine hours. When the school day begins early, their sleep needs are not satisfied.

This sleep “phase delay” strengthens with pubertal growth. But today's teenagers—with more evening social activities, part-time jobs, and bedrooms equipped with screen media—get much less sleep than teenagers of previous generations. Sleep-deprived adolescents display declines in executive function and both cognitive and emotional self-regulation. As a result, they are more likely to achieve less well in school; suffer from anxiety, irritability, and depressed mood; and engage in high-risk behaviors that result in motor vehicle collisions and arrests for delinquency (Bryant & Gómez, 2015; Carskadon, 2011; Meldrum, Barnes, & Hay, 2015). Sleep rebound on weekends sustains the pattern by leading to difficulty falling asleep on subsequent evenings. Later school start times ease but do not eliminate sleep loss (Wahlstrom et al., 2014). Educating teenagers about the importance of sleep is vital.

## The Psychological Impact of Pubertal Events

**11.5** Explain adolescents' reactions to the physical changes of puberty.

**11.6** Describe the impact of pubertal timing on adolescent adjustment, noting sex differences.

Think back to your late elementary and middle school days. As you reached puberty, how did your feelings about yourself and your relationships with others change? Research reveals that pubertal events affect adolescents' self-image, mood, and interaction with parents and peers. Some outcomes are a response to dramatic physical change, whenever it occurs. Others have to do with pubertal timing.

## Reactions to Pubertal Changes

Two generations ago, menarche was often traumatic. Today, girls commonly react with “surprise,” undoubtedly due to the sudden onset of the event. Otherwise, they typically report a mixture of positive and negative emotions (Chang, Hayter, & Wu, 2010; DeRose & Brooks-Gunn, 2006). Yet wide individual differences exist that depend on prior knowledge and support from family members, which in turn are influenced by cultural attitudes toward puberty and sexuality.

For girls who have no advance information, menarche can be shocking and disturbing. And cultural or religious views of menstruation as unclean, embarrassing, or a source of weakness requiring restriction of activities also promote distressed reactions (Marván & Alcalá-Herrera, 2014). Unlike 50 to 60 years ago, today few girls in developed countries are uninformed, a shift that is probably due to parents' greater willingness to discuss sexual matters and to the spread of health education classes (Omar, McElderry, & Zakharia, 2003). Almost all girls get some information from their mothers. And some evidence suggests that compared with European-American families, African-American families may better prepare girls for menarche, treat it

as an important milestone, and express less conflict over girls reaching sexual maturity—factors that lead African-American girls to react more favorably (Martin, 1996).

Like girls' reactions to menarche, boys' responses to spermarche reflect mixed feelings. Virtually all boys know about ejaculation ahead of time, but many say that no one spoke to them before or during puberty about physical changes (Omar, McElderry, & Zakharia, 2003). Usually they get their information from reading material or websites. Even boys who had advance information often say that their first ejaculation occurred earlier than they expected and that they were unprepared for it. Whereas almost all girls eventually tell a friend that they are menstruating, far fewer boys tell anyone about spermarche (DeRose & Brooks-Gunn, 2006; Downs & Fuller, 1991). Overall, boys get much less social support than girls for the changes of puberty. They might benefit, especially, from opportunities to ask questions and discuss feelings with a sympathetic parent or health professional.

Many tribal and village societies celebrate the onset of puberty with an *initiation ceremony*, a ritualized announcement to the community that marks an important change in privilege and responsibility. Consequently, young people know that reaching puberty is a significant milestone in their culture. In contrast, Western societies grant little formal recognition to movement from childhood to adolescence or from adolescence to

adulthood. Ceremonies such as the Jewish bar or bat mitzvah and the *quinceañera* in Hispanic communities (celebrating a 15-year-old girl's sexual maturity and marriage availability) resemble initiation ceremonies, but only within the ethnic or religious subculture. They do not mark a significant change in social status in the larger society.

Instead, Western adolescents are granted partial adult status at many different ages—for example, an age for starting employment, for driving, for leaving high school, for voting, and for drinking. And in some contexts (at home and at school), they may still be regarded as children. The absence of a widely accepted marker of physical and social maturity makes the process of becoming an adult more confusing.

## Pubertal Change, Emotion, and Social Behavior

A common belief is that puberty has something to do with adolescent moodiness and the desire for greater physical and psychological separation from parents. Let's see what research says about these relationships.

**Adolescent Moodiness.** Higher pubertal hormone levels are linked to greater moodiness, but only modestly so (Graber, Brooks-Gunn, & Warren, 2006). What other factors might contribute? In several studies, the moods of children, adolescents, and adults were monitored by having them carry electronic pagers, beeping them at random intervals, and asking them to write down what they were doing, whom they were with, and how they felt.

As expected, adolescents reported less favorable moods than school-age children and adults (Larson & Lampman-Petratis, 1989; Larson et al., 2002). But negative moods were linked to a greater number of negative life events, such as difficulties with parents, disciplinary actions at school, and breaking up with a boyfriend or girlfriend. Negative events increased steadily from childhood to adolescence, and teenagers also reacted to them with greater emotion than children (Larson & Ham, 1993). (Recall that stress reactivity is heightened by changes in the brain's emotional/social network during puberty.)

Compared with the moods of older adolescents and adults, those of younger adolescents (ages 12 to 16) were less stable, often shifting between cheerful and sad. These mood swings were strongly related to situational changes. High points of adolescents' days were times spent with peers and in self-chosen leisure activities. Low points tended to occur in adult-structured settings—class, job, and religious services. Furthermore, emotional highs coincided with Friday and Saturday evenings, especially in high school. Going out with friends and romantic partners increases so dramatically during adolescence that it becomes a “cultural script” for what is *supposed* to happen (Larson & Richards, 1998). Consequently, teenagers who spend weekend evenings at home often feel profoundly lonely. Fortunately, frequent reports of negative mood level off in late adolescence (Natsuaki, Biehl, & Ge, 2009).

© MARMADUKE ST. JOHN/ALAMY

In Hispanic communities, the quinceañera, celebrated at age 15, is a rite of passage honoring a girl's journey from childhood to maturity. However, the ceremony does not mark a meaningful change in social status in the larger society.

**Parent–Child Relationships.** Sabrina’s father noticed that as his children entered adolescence, they kept their bedroom doors closed, resisted spending time with the family, and became more argumentative. Sabrina and her mother squabbled over Sabrina’s messy room (“It’s *my* room, Mom. You don’t have to live in it!”). And Sabrina protested the family’s regular weekend visit to Aunt Gina’s (“Why do I have to go *every* week?”). Research shows that puberty is related to a rise in intensity of parent–child conflict, and to fluctuations between positive and negative parent–child interaction, that persists into middle adolescence (Gure, Ucanok, & Sayil, 2006; Marceau, Ram, & Susman, 2015; McGue et al., 2005).

Why should young teenagers’ more adultlike appearance trigger these disputes? The association may have adaptive value. Among nonhuman primates, the young typically leave the family group around the time of puberty. The same is true in many village and tribal cultures (Lancy, 2008; Schlegel & Barry, 1991). Departure of young people discourages sexual relations between close blood relatives. But adolescents in industrialized nations, who are still economically dependent on parents, cannot leave the family. Consequently, a substitute seems to have emerged: psychological distancing.

As children become physically mature, they demand to be treated in adultlike ways. And as we will see, adolescents’ new powers of reasoning may also contribute to a rise in family tensions. Parent–adolescent disagreements focus largely on everyday matters such as driving, dating partners, and curfews (Adams & Laursen, 2001). But beneath these disputes lie serious concerns: parental efforts to protect teenagers from substance use, auto accidents, and early sexual activity. The larger the gap between parents’ and adolescents’ views of teenagers’ readiness for new responsibilities, the more they quarrel (Deković, Noom, & Meeus, 1997).

© CATCHLIGHT VISUAL SERVICES/ALAMY

Puberty brings an increase in parent–child conflict—psychological distancing that may, in part, be a modern substitute for physical departure from the family. Parents and adolescents often argue over the young person’s readiness for new responsibilities.

Parent–daughter conflict tends to be more intense than conflict with sons, perhaps because parents place more restrictions on girls (Allison & Schultz, 2004). But most disputes are mild, and by late adolescence, only a small minority of families experience continuing friction. In a longitudinal investigation of parent–child conflict-resolution strategies spanning early to late adolescence, after an initial increase, adolescents displayed fewer angry behaviors, and parents’ angry responses also declined. At the same time, teenagers and parents increasingly used positive problem solving, such as compromise and reasoning (Van Doorn, Branje, & Meeus, 2011). And throughout adolescence, positive problem solving greatly exceeded angry confrontations.

### LOOK and LISTEN

Interview several parents and/or 12- to 14-year-olds about recent changes in parent–child relationships. Has intensity of conflict increased? Over what issues?

## Pubertal Timing

“All our children were early maturers,” said Franca during the parents’ discussion group. “The three boys were tall by age 12 or 13, but it was easier for them. They felt big and important. Sabrina was skinny as a little girl, but now she says she is too fat and needs to diet. She thinks about boys and doesn’t concentrate on her schoolwork.”

Findings of several studies match the experiences of Sabrina and her brothers. Both adults and peers viewed early-maturing boys as relaxed, independent, self-confident, and physically attractive. Popular with agemates, they tended to hold leadership positions in school and to be athletic stars. Late-maturing boys often experienced transient emotional difficulties, until they caught up physically with their peers (Brooks-Gunn, 1988; Huddleston & Ge, 2003). But early-maturing boys, though viewed as well-adjusted, reported more psychological stress, depressed mood, and problem behaviors (sexual activity, smoking, drinking, aggression, delinquency) than both their on-time and later-maturing agemates (Natsuaki, Biehl, & Ge, 2009; Negriff, Susman, & Trickett, 2011; Susman & Dorn, 2009).

In contrast, early-maturing girls were unpopular, withdrawn, lacking in self-confidence, anxious, and prone to depression, and they held few leadership positions (Blumenthal et al., 2011; Galvao et al., 2014; Ge, Conger, & Elder, 1996; Graber, Brooks-Gunn, & Warren, 2006; Jones & Mussen, 1958). And like early-maturing boys, they were more involved in deviant behavior (smoking, drinking, sexual activity, delinquency) (Arim et al., 2011; Mrug et al., 2014; Negriff, Susman, & Trickett, 2011). In contrast, their later-maturing counterparts were regarded as physically attractive, lively, sociable, and leaders at school.

Two factors largely account for these trends: (1) how closely the adolescent’s body matches cultural ideals of physical attractiveness, and (2) how well young people fit in physically with their peers.

**The Role of Physical Attractiveness.** Flip through your favorite popular magazine. You will see evidence of our society's view of an attractive female as thin and long-legged and of a good-looking male as tall, broad-shouldered, and muscular. The female image is a girlish shape that favors the late developer. The male image fits the early-maturing boy.

Consistent with these preferences, early-maturing European-American girls tend to report a less positive **body image**—conception of and attitude toward their physical appearance—than their on-time and late-maturing agemates. Compared with African-American and Hispanic girls, European-American girls are more likely to have internalized the cultural ideal of a thin female body (Rosen, 2003; Williams & Currie, 2000). Although boys are less consistent, early, rapid maturers are more likely to be satisfied with their physical characteristics (Alsaker, 1995; Sinkkonen, Anttila, & Siimes, 1998).

Body image is a strong predictor of young people's self-esteem (Harter, 2012). But the negative effects of pubertal timing on body image and—as we will see next—emotional adjustment are greatly amplified when accompanied by other stressors (Stice, 2003).

**The Importance of Fitting in with Peers.** Because early-maturing adolescents of both sexes feel physically “out of place” when with their agemates, they often seek out older companions, who may encourage them into activities they are not yet ready to handle. And pubertal hormonal influences on the brain's emotional/social network are stronger for early maturers, further magnifying their receptiveness to sexual activity, drug and alcohol use, and delinquent acts (Ge et al., 2002; Steinberg, 2008). Perhaps as a result, early maturers of both sexes more often report feeling emotionally stressed and decline in academic performance (Mendle, Turkheimer, & Emery, 2007; Natsuaki, Biehl, & Ge, 2009).

At the same time, the young person's context greatly increases the likelihood that early pubertal timing will lead to negative outcomes. Early maturers in economically disadvantaged neighborhoods are especially vulnerable to establishing ties with deviant peers—associations that heighten defiant, hostile behavior (Obeidallah et al., 2004). And because families in such neighborhoods tend to be exposed to chronic, severe stressors and to have few social supports, these early maturers are also more likely to experience harsh, inconsistent parenting, which, in turn, predicts deviant peer associations as well as antisocial behavior and depressive symptoms (Benoit, Lacourse, & Claes, 2013; Ge et al., 2002, 2011).

**Long-Term Consequences.** Do the effects of pubertal timing last? Follow-up research reveals that early-maturing girls, especially, are at risk for lasting difficulties. In one study, depression and frequently changing sexual partners persisted into early adulthood among early-maturing girls, with depression evident mainly in those who had displayed the severest adolescent conduct problems (Copeland et al., 2010). In another study, which followed young people from age 14 to 24,

Early maturers often seek out the companionship of older adolescents, who increase their risk for early sexual activity, drug use, and delinquency. In economically disadvantaged neighborhoods, early maturers are especially vulnerable to establishing ties with deviant peers.

early-maturing boys showed good adjustment. But early-maturing girls reported poorer-quality relationships with family and friends, smaller social networks, and lower life satisfaction in early adulthood than did their on-time counterparts (Graber et al., 2004).

Recall that childhood family conflict and harsh parenting are linked to earlier pubertal timing, more so for girls than for boys (see page 373). Perhaps many early-maturing girls enter adolescence with emotional and social difficulties. As the stresses of puberty interfere with school performance and lead to unfavorable peer pressures, poor adjustment may extend and deepen.

Clearly, interventions that target at-risk early-maturing youths are needed. These include educating parents and teachers and providing adolescents with counseling and social supports so they will be better prepared to handle the emotional and social challenges of this transition.

## Ask yourself

**CONNECT** How might adolescent moodiness contribute to psychological distancing between parents and adolescents? (*Hint:* Think about bidirectional influences in parent–child relationships.)

**APPLY** As a school-age child, Chloe enjoyed leisure activities with her parents. Now, as a 14-year-old, she spends hours in her room and resists going on weekend family excursions. Explain Chloe's behavior.

**REFLECT** Recall your own reactions to the physical changes of puberty. Are they consistent with research findings? Explain.

## Health Issues

- 11.7** Describe nutritional needs during adolescence, and cite factors related to eating disorders.
- 11.8** Discuss social and cultural influences on adolescent sexual attitudes and behavior.
- 11.9** Cite factors involved in development of sexual orientation.
- 11.10** Discuss factors related to sexually transmitted infections and teenage pregnancy and parenthood, noting prevention and intervention strategies.
- 11.11** What personal and social factors are related to adolescent substance use and abuse?

The arrival of puberty brings new health issues related to the young person's efforts to meet physical and psychological needs. As adolescents attain greater autonomy, their personal decision making becomes important, in health as well as other areas. Yet none of the health concerns we are about to discuss can be traced to a single cause. Rather, biological, psychological, family, peer, and cultural factors jointly contribute.

### Nutritional Needs

When their sons reached puberty, Franca and Antonio reported a “vacuum cleaner effect” in the kitchen as the boys routinely emptied the refrigerator. Rapid body growth leads to a dramatic increase in nutritional requirements, at a time when the diets of many young people are the poorest. Of all age groups, adolescents are the most likely to skip breakfast (a practice linked to overweight and obesity), eat on the run, and consume empty calories (Piernas & Popkin, 2011; Ritchie et al., 2007).

Fast-food restaurants, where teenagers often gather, have begun to offer some healthy menu options, and many schools now offer more nutritious choices (French & Story, 2013). But adolescents need guidance in selecting these alternatives. Sweets, soft drinks, pizza, and French fries still figure prominently in the diets of many young people, especially those from low-SES families (Poti, Slining, & Popkin, 2014; Slining, Mathias, & Popkin, 2013).

One of the most common nutritional problems of adolescence is iron deficiency. Iron requirements increase to a maximum during the growth spurt and remain high among girls because of iron loss during menstruation. A tired, irritable teenager may be suffering from anemia rather than unhappiness and should have a medical checkup. Many adolescents—especially girls—do not get enough calcium and are also deficient in riboflavin (vitamin B<sub>2</sub>) and magnesium, both of which support metabolism (Rozen, 2012).

Frequency of family meals is strongly associated with greater intake of fruits, vegetables, grains, and calcium-rich foods and reduced soft drink and fast-food consumption (Burgess-Champoux et al., 2009; Fiese & Schwartz, 2008). But compared to families with younger children, those with adolescents eat fewer meals together. In addition to their other benefits (see page

60 in Chapter 2 and page 295 in Chapter 9), family meals can greatly improve teenagers' diets.

### Eating Disorders

Concerned about her daughter's desire to lose weight, Franca explained to Sabrina that she was really quite average in build for an adolescent girl and reminded her that her Italian ancestors had considered a plump female body more beautiful than a thin one. Girls who reach puberty early, who are very dissatisfied with their body image, and who grow up in homes where concern with weight and thinness is high are at risk for eating problems. Body dissatisfaction and severe dieting are strong predictors of an eating disorder in adolescence (Rohde, Stice, & Marti, 2014). Disturbed eating is highest in Western nations, but with the spread of Western media and cultural values, Africa, Asia, and the Middle East are increasingly affected (Pike, Hoek, & Dunne, 2014). The three most serious eating disorders are anorexia nervosa, bulimia nervosa, and binge-eating disorder.

**Anorexia Nervosa.** *Anorexia nervosa* is a tragic eating disorder in which young people starve themselves because of a compulsive fear of getting fat. About 1 percent of North American and Western European teenage girls are affected. During the past half-century, cases have increased sharply, fueled by cultural admiration of female thinness. In the United States, Asian-American, European-American, and Hispanic girls are at greater risk than African-American girls, whose greater satisfaction with their body image may offer some protection (American Psychiatric Association, 2013; Martin et al., 2015; Ozer & Irwin, 2009). Boys account for 10 to 15 percent of anorexia cases; up to half of these are gay or bisexual young people, who may be uncomfortable with a strong, bulky appearance or influenced by the cultural ideal of a lean but muscular male body (Darcy, 2012; Raevuori et al., 2009).

Individuals with anorexia have an extremely distorted body image. Even after becoming severely underweight, they see themselves as too heavy. Most go on self-imposed diets so strict that they struggle to avoid eating in response to hunger. To enhance weight loss, they exercise strenuously.

In their attempt to reach “perfect” slimness, individuals with anorexia lose 25 to 50 percent of their body weight. A normal menstrual cycle requires about 15 percent body fat, so many girls with anorexia experience delayed menarche or disrupted menstrual cycles. Malnutrition causes pale skin, brittle discolored nails, fine dark hairs all over the body, and extreme sensitivity to cold. If it continues, the heart muscle can shrink, the kidneys can fail, and irreversible brain damage and loss of bone mass can occur. About 5 percent of individuals with anorexia eventually die of the disorder, due to physical complications or suicide (American Psychiatric Association, 2013).

Forces within the person, the family, and the larger culture give rise to anorexia nervosa. Identical twins share the disorder more often than fraternal twins, indicating a genetic influence. Abnormalities in neurotransmitters in the brain, linked to anxiety and impulse control, may make some individuals more

Aiva, a 16-year-old anorexia nervosa patient, is shown at left on the day she entered treatment—weighing just 77 pounds—and, at right, after a 10-week treatment program. Less than 50 percent of young people with anorexia recover fully.

susceptible (Phillipou, Rossell, & Castle, 2014; Pinheiro, Root, & Bulik, 2011). Many young people with anorexia have unrealistically high standards for their own behavior and performance, are emotionally inhibited, and avoid intimate ties outside the family. Consequently, they are often excellent students who are responsible and well-behaved. But as we have also seen, the societal image of “thin is beautiful” contributes to the poor body image of many girls—especially early-maturing girls, who are at greatest risk (Hoste & Le Grange, 2013).

In addition, parent–adolescent interactions reveal problems related to adolescent autonomy. Often the mothers of these girls have high expectations for physical appearance, achievement, and social acceptance and are overprotective and controlling. Fathers tend to be either controlling or uninvolved. These parental attributes may contribute to affected girls’ persistent anxiety and fierce pursuit of perfection in achievement, respectable behavior, and thinness (Deas et al., 2011; Kaye, 2008). Nevertheless, it remains unclear whether maladaptive parent–child relationships precede the disorder, emerge as a response to it, or both.

Because individuals with anorexia usually deny or minimize the seriousness of their disorder, treatment is difficult. Hospitalization is often necessary to prevent life-threatening malnutrition. The most successful treatment is family therapy and medication to reduce anxiety and neurotransmitter imbalances (Hoste & Le Grange, 2013). Still, less than 50 percent of young people with anorexia recover fully. For many, eating problems continue in less extreme form. About 10 percent show signs of a less severe, but nevertheless debilitating, disorder: bulimia nervosa.

**Bulimia Nervosa.** In **bulimia nervosa**, young people (again, mainly girls, but gay and bisexual boys are also vulnerable)

engage in binge eating, followed by compensatory efforts to avoid weight gain, such as deliberate vomiting, purging with laxatives, excessive exercise, or fasting (American Psychiatric Association, 2013). Bulimia typically appears in late adolescence and is more common than anorexia nervosa, affecting about 2 to 4 percent of teenage girls, only 5 percent of whom previously suffered from anorexia. Bulimia is not consistently linked to ethnicity.

Twin studies show that bulimia, like anorexia, is influenced by heredity (Thornton, Mazzeo, & Bulik, 2011). Overweight and early menarche increase the risk. Some adolescents with bulimia, like those with anorexia, are perfectionists. But most are impulsive, sensation-seeking young people who are especially prone to act irrationally when distressed and who engage in petty shoplifting, alcohol abuse, and other risky behaviors (Pearson, Wonderlich, & Smith, 2015). And although girls with bulimia, like those with anorexia, are pathologically anxious about gaining weight, they may have experienced their parents as disengaged and emotionally unavailable rather than as controlling (Fassino et al., 2010).

In contrast to young people with anorexia, those with bulimia usually feel depressed and guilty about their abnormal eating habits, and many report suicidal thoughts (Bodell, Joiner, & Keel, 2013). Because affected individuals desperately want help, bulimia is usually easier to treat than anorexia, through support groups, nutrition education, training in changing eating habits, and anti-anxiety, antidepressant, and appetite-control medication (Hay & Bacaltchuk, 2004).

**Binge-Eating Disorder.** Between 2 and 3 percent of adolescent girls and close to 1 percent of boys experience episodes of **binge-eating disorder**—binging at least once a week for three months or longer, without compensatory purging, exercise, or fasting (American Psychiatric Association, 2013; Smink et al., 2014). Binge-eating disorder, like bulimia, is unrelated to ethnicity. It typically leads to overweight and obesity, but binge eaters do not engage in the prolonged, restrictive dieting characteristic of anorexia and bulimia.

As with other eating disorders, binge-eating disorder is associated with social adjustment difficulties, and many binge eaters—similar to individuals with bulimia—experience severe emotional distress and suicidal thoughts (Stice, Marti, & Rohde, 2013). Effective treatments resemble those used for bulimia.

## Sexuality

Sabrina’s 16-year-old brother Louis and his girlfriend Cassie hadn’t planned to have intercourse—it “just happened.” After dating Louis for two months, Cassie began to wonder, “Will he think I’m normal if I don’t have sex with him? If he wants to and I say no, will I lose him?” Both young people knew their parents wouldn’t approve. In fact, when Franca and Antonio noticed how attached Louis was to Cassie, they talked to him about the importance of waiting and the dangers of pregnancy. But that Friday evening, Louis and Cassie’s feelings for each other seemed overwhelming. “If I don’t make a move,” Louis thought, “will she think I’m a wimp?”

© LAURA DWIGHT PHOTOGRAPHY

Cultural attitudes will profoundly affect the way these teenagers, who are just beginning to explore their sexual attraction to each other, learn to manage sexuality in social relationships.

With the arrival of puberty, hormonal changes—in particular, the production of androgens in young people of both sexes—lead to an increase in sex drive (Best & Fortenberry, 2013). In response, adolescents become very concerned about managing sexuality in social relationships. Improved cognitive capacities involving perspective taking and self-reflection affect their efforts to do so. Yet like the eating behaviors we have just discussed, adolescent sexuality is heavily influenced by the young person's social context.

**The Impact of Culture.** When did you first learn about sex, and how? Was sex discussed openly in your family, or was it treated with secrecy? Exposure to sex, education about it, and efforts to limit the sexual curiosity of children and adolescents vary widely around the world.

Despite the prevailing image of sexually free adolescents, sexual attitudes in North America are relatively restrictive. Typically, parents provide little or no information about sex, discourage sex play, and rarely talk about sex in children's presence. When young people become interested in sex, only about half report getting information from parents about intercourse, pregnancy prevention, and sexually transmitted infections. Many parents avoid meaningful discussions about sex out of fear of embarrassment or concern that the adolescent will not take them seriously (Wilson et al., 2010). Yet warm, open give-and-take is associated with teenagers' adoption of parents' views, discussions about sexual health with dating partners, and reduced sexual risk taking (Commendador, 2010; Widman et al., 2014).

Adolescents who do not get information about sex from their parents are likely to learn from friends, siblings, books, magazines, movies, TV, and the Internet (Sprecher, Harris, & Meyers, 2008). Among TV shows that adolescents prefer, more than 80 percent contain sexual content. Most depict partners as spontaneous and passionate, taking no steps to avoid pregnancy or sexually transmitted infections, and experiencing no negative consequences. Teenagers' exposure to sexualized media predicts increased sexual activity, pregnancy, and sexual harassment behaviors (offensive name-calling or touching, pressuring a peer for a date), even after many other relevant factors are controlled (Brown & L'Engle, 2009; Roberts, Henriksen, & Foehr, 2009; Wright, Malamuth, & Donnerstein, 2012).

Not surprisingly, adolescents who are prone to engage in early sex choose to consume more sexualized media (Steinberg & Monahan, 2011; Vandenbosch & Eggermont, 2013). Still, the Internet is a hazardous "sex educator." In a survey of a large sample of U.S. 10- to 17-year-old Web users, 42 percent said they had viewed online pornographic websites (images of naked people or people having sex) while surfing the Internet in the past 12 months. Of these, 66 percent indicated they had encountered the images accidentally and did not want to view them (Wolak, Mitchell, & Finkelhor, 2007). Youths who felt depressed, had been bullied by peers, or were involved in delinquent activities had more encounters with Internet pornography, which may have intensified their adjustment problems.

Consider the contradictory messages young people receive. On one hand, adults express disapproval of sex at a young age and outside of marriage. On the other hand, the social environment extols sexual excitement, experimentation, and promiscuity. American teenagers are left bewildered, poorly informed about sexual facts, and with little sound advice on how to conduct their sex lives responsibly.

**Adolescent Sexual Attitudes and Behavior.** Although differences among subcultural groups exist, sexual attitudes of U.S. adolescents and adults have become more liberal over the past half century. Compared with previous generations, more people approve of sexual intercourse before marriage (Elias, Fullerton, & Simpson, 2013; Rifkin, 2014). During the past 15 years, adolescents have swung slightly back toward more conservative sexual beliefs, largely in response to the risk of sexually transmitted infections, especially AIDS, and to teenage sexual abstinence programs sponsored by schools and religious organizations (Akers et al., 2011; Ali & Scelfo, 2002).

Trends in adolescents' sexual behavior are consistent with their attitudes. Rates of nonmarital sex among U.S. young people rose for several decades but have recently declined (Martinez & Abma, 2015). Nevertheless, as Figure 11.4 illustrates, a substantial percentage of U.S. young people are sexually active by ages 15 to 16.

The quality of adolescent sexual experiences varies, depending on circumstances. About 70 percent of sexually active teenagers report that they first had sex with a steady dating partner, and most have only one or two partners during high school. But 12 percent of high school students report having sexual relations

**FIGURE 11.4** U.S. adolescents who report ever having had sexual intercourse. Most U.S. adolescents become sexually active during the high school years. Boys tend to have their first intercourse earlier than girls, but in general, boys and girls' rates of sexual intercourse are similar. (Based on Martinez & Abma, 2015.)

with four or more partners (Kann et al., 2016; Wildsmith et al., 2012). Mutually consensual sexual activity in the context of a stable, caring romantic relationship can be a positive and satisfying experience for older adolescents. But when teenagers engage in casual sex, or have sex when they have been drinking or using drugs, they often report negative feelings, including guilt and depression (Harden, 2014).

**Characteristics of Adolescents Who Engage in Early Sexual Activity.** A variety of adverse personal, family, peer, and educational characteristics are linked to early and frequent teenage sexual activity. These include childhood impulsivity, weak sense of personal control over life events, early pubertal timing, parental divorce, single-parent and stepfamily homes, large family size, little or no religious involvement, weak parental monitoring, disrupted parent-child communication, sexually active friends and older siblings, poor school performance, lower educational aspirations, and tendency to engage in norm-violating acts, including alcohol and drug use and delinquency (Conduct Problems Prevention Research Group, 2014; Diamond, Bonner, & Dickenson, 2015; Zimmer-Gembeck & Helfand, 2008).

Because many of these factors are associated with growing up in a low-income family, it is not surprising that early sexual activity is more common among young people from economically disadvantaged homes. Living in a neighborhood high in physical deterioration, crime, and violence also increases the likelihood that teenagers will be sexually active (Best & Fortenberry, 2013). In such neighborhoods, social ties are weak, adults exert little oversight and control over adolescents' activities, negative peer influences are widespread, and teenagers are unlikely to consider the impact of early parenthood on their

current and future lives. In fact, the high rate of early sexual activity among African-American teenagers—8 percent report having had sexual intercourse before age 13, compared with 4 percent of all U.S. young people—may be largely explained by widespread poverty in the black population (Kann et al., 2016; Kaplan et al., 2013).

**Contraceptive Use.** Although adolescent contraceptive use has increased in recent years (see Figure 11.5), about 14 percent of sexually active teenagers in the United States are at risk for unintended pregnancy because they do not use contraception consistently (Kann et al., 2016). Why do so many fail to take precautions? Typically, teenagers respond, “I was waiting until I had a steady boyfriend” or “I wasn’t planning to have sex.”

As our discussion of cognitive development will reveal, although adolescents can consider many possibilities when faced with a problem, they often fail to apply this reasoning to everyday situations. We have seen that in the midst of everyday peer pressures and heightened emotion, self-regulation is difficult for teenagers, who often overlook the potential consequences of risky behaviors. They are least likely to use condoms in relatively new relationships in which they feel high trust or love and are having sex often (Ewing & Bryan, 2015).

Adolescents who report good relationships with parents and who talk openly with them about sex and contraception are more likely to use birth control (Widman et al., 2014). But few believe their parents would be understanding and supportive. School sex

**FIGURE 11.5** Contraceptive use at last intercourse among sexually active U.S. high school students, 1991 to 2015. Adolescents' use of contraceptives—especially condoms—increased throughout the 1990s and early 2000s. More recently, overall rates of contraceptive use stabilized. At the same time, adolescents increasingly chose methods other than the condom that are effective, most commonly hormonal options—the pill, patch, or vaginal ring. (Based on Kann et al., 2016.)

## Social Issues: Health

### Lesbian, Gay, and Bisexual Youths: Coming Out to Oneself and Others

Cultures vary widely in their acceptance of sexual minorities. In the United States, societal attitudes toward lesbian, gay, and bisexual people have become more accepting, but prejudice remains widespread (Pew Research Center, 2013d). This makes forming a sexual identity more challenging for sexual minority youths than for their heterosexual counterparts.

Wide variation in sexual identity formation exists, depending on personal, family, and community factors. Yet interviews with gay and lesbian adolescents and adults reveal that many (though not all) move through a three-phase sequence in coming out to themselves and others.

#### Feeling Different

Many gay men and lesbians say that they felt different from other children when they were young. Typically, this first sense of their biologically determined sexual orientation appears between ages 6 and 12, in play interests more like those of the other gender (Rahman &

Wilson, 2003). Boys may find that they are less interested in sports, more drawn to quieter activities, and more emotionally sensitive than other boys; girls that they are more athletic and active than other girls. By age 10, many of these children start to engage in *sexual questioning*—wondering why the typical heterosexual orientation does not apply to them.

#### Confusion

With the arrival of puberty, feeling different clearly encompasses feeling sexually different. Although wide variation exists, on average, boys begin to think they are gay at around age 10 and know for sure at around age 15 (Pew Research Center, 2013d). Awareness tends to emerge a few years later for girls, around 13 and 18, respectively, perhaps because social pressures toward heterosexuality are particularly intense for adolescent girls.

Realizing that same-sex attraction has personal relevance generally sparks additional confusion. A few adolescents resolve their discomfort by crystallizing a lesbian, gay, or

bisexual identity quickly, with a flash of insight into their sense of being different. But most experience an inner struggle and a deep sense of isolation—outcomes intensified by lack of role models and social support (Safren & Pantalone, 2006).

Some throw themselves into activities they associate with heterosexuality. Boys may go out for athletic teams; girls may drop softball and basketball in favor of dance. And many lesbian and gay youths (more females than males) try heterosexual dating, sometimes to hide their sexual orientation and at other times to develop intimacy skills that they later apply to same-sex relationships (D'Augelli, 2006). Those who are extremely troubled and guilt-ridden may escape into alcohol, drugs, and suicidal thinking. As Chapter 16 will reveal, suicide attempts are unusually high among lesbian, gay, and bisexual young people.

#### Self-Acceptance

By the end of adolescence, the majority of lesbian, gay, and bisexual teenagers accept

education classes, as well, often leave teenagers with incomplete or incorrect knowledge. Some do not know where to get birth control counseling and devices or how to discuss contraception with a partner. And those engaged in high-risk sexual behaviors are especially likely to worry that a doctor or family planning clinic might not keep their visits confidential (Lehrer et al., 2007). Most of these young people forgo essential health care but continue to have sex without contraception.

**Sexual Orientation.** So far, we have focused only on heterosexual behavior. About 5 percent of U.S. high school students identify as lesbian, gay, or bisexual, and another 2 to 3 percent report being unsure of their sexual orientation (Kann et al., 2011). An unknown number experience same-sex attraction but have not come out to friends or family (see the Social Issues: Health box above). Adolescence is an equally crucial time for the sexual development of these individuals, and societal attitudes, again, loom large in how well they fare.

Heredity makes an important contribution to sexual orientation: Identical twins of both sexes are more likely than fraternal twins to share a homosexual orientation; so are biological (as opposed to adoptive) relatives (Kendler et al., 2000; Långström et al., 2010). Furthermore, male homosexuality tends to be more

common on the maternal than on the paternal side of families, suggesting that it may be X-linked (see Chapter 2). Indeed, one gene-mapping study found that among 40 pairs of gay brothers, 33 (82 percent) had an identical segment of DNA on the X chromosome (Hamer et al., 1993). One or several genes in that region might predispose males to develop same-sex attraction.

How might heredity influence sexual orientation? According to some researchers, certain genes affect the level or impact of prenatal sex hormones, which modify brain structures in ways that induce homosexual feelings and behavior (Bailey et al., 1995; LeVay, 1993). Keep in mind, however, that environmental factors can also alter prenatal hormones. Girls exposed prenatally to very high levels of androgens or estrogens—either because of a genetic defect or from drugs given to the mother to prevent miscarriage—are more likely to develop lesbian or bisexual orientations (Hines, 2011b). Furthermore, gay men tend to be later in birth order and to have a higher-than-average number of older brothers (Bogaert & Skorska, 2011; VanderLaan et al., 2014). Perhaps mothers with several male children sometimes produce antibodies to androgens, reducing the prenatal impact of male sex hormones on the brains of later-born boys.

Stereotypes and misconceptions about homosexuality and bisexuality persist. For example, contrary to common belief,

their sexual identity. But they face another crossroad: whether to tell others. Stigma against their sexual orientation leads some to decide that disclosure is impossible. When they do come out, sexual minority youths often face peer hostility, including verbal abuse and physical attacks. These experiences trigger intense emotional distress, depression, school truancy, and drug use in victims (Dragowski et al., 2011; Rosario & Schrimshaw, 2013).

Nevertheless, many young people eventually acknowledge their sexual orientation publicly, usually by telling trusted friends first. Once teenagers establish a same-sex sexual or romantic relationship, many come out to parents. Few parents respond with severe rejection; most are either positive or slightly negative and disbelieving. Still, lesbian, gay, and bisexual young people report lower levels of family support than their heterosexual agemates (McCormack, Anderson, & Adams, 2014; Needham & Austin, 2010). Yet parental understanding is a key predictor of favorable adjustment—including reduced *internalized homophobia*, or societal prejudice turned against the self (Bregman et al., 2013).

When people react positively, coming out strengthens the young person's sexual identity as valid, meaningful, and fulfilling. Contact with lesbian, gay, and bisexual peers is important for reaching this phase, and changes in society permit many adolescents in urban areas to attain it earlier than their counterparts did a decade or two ago. Gay and lesbian communities exist in large cities, along with specialized interest groups, social clubs, religious groups, newspapers, and periodicals. But teenagers in small towns and rural areas may have difficulty meeting other sexual minority youths and finding a supportive environment. These adolescents have a special need for caring adults and peers who can help them find self- and social acceptance.

Lesbian, gay, and bisexual teenagers who succeed in coming out to themselves and

others integrate their sexual orientation into a broader sense of identity, a process we will address in Chapter 12. As a result, energy is freed for other aspects of psychological growth. In sum, coming out can foster many facets of adolescent development, including self-esteem, psychological well-being, and relationships with family and friends.

Lesbian, gay, bisexual, and transgender high school students and their allies participate in an annual Youth Pride Festival and March. When peers react with acceptance, coming out strengthens the young person's sexual identity as valid, meaningful, and fulfilling.

© MARILYN HUMPHRIES/THE IMAGE WORKS

most sexual minority adolescents and adults are not “gender-deviant” in dress or behavior. And attraction to members of the same sex is not limited to lesbian, gay, and bisexual teenagers. In recent surveys, between 17 and 78 percent of teenagers who reported sexual experiences with same-sex partners identified as heterosexual (Kann et al., 2011). And a study of lesbian, bisexual, and “unlabeled” young women confirmed that bisexuality is not, as often assumed, a transient state (Diamond, 2008). Over a 10-year period, most reported stable proportions of same-sex versus other-sex attractions over time.

The evidence to date indicates that genetic and prenatal biological influences contribute substantially to homosexuality. The origins of bisexuality are not yet known.

## Sexually Transmitted Infections

Sexually active adolescents, regardless of sexual orientation, are at risk for sexually transmitted infections (STIs). Young people from 15 to 24 have the highest rates of STIs of all age groups (Centers for Disease Control and Prevention, 2015l). In recent years, U.S. rates have risen: 1 out of 5 sexually active teenagers contracts an STI each year—a rate three or more times that of Canada and Western Europe (Greydanus et al., 2012; Public

Health Agency of Canada, 2015). Teenagers at greatest risk are the same ones most likely to engage in irresponsible sexual behavior: economically disadvantaged young people who feel a sense of hopelessness. Left untreated, STIs can lead to sterility and life-threatening complications.

By far the most serious STI is HIV/AIDS. In contrast to other Western nations, where the incidence of HIV infection among people under age 30 is low, one-fourth of U.S. HIV cases are young people between ages 13 and 24. Because AIDS symptoms typically do not emerge until 8 to 10 years after HIV infection, many young adults diagnosed with HIV or AIDS contracted the virus during adolescence. Males who have sex with HIV-positive same-sex partners account for most of these cases. But one-fourth are due to heterosexual spread of the disease, mostly through male-to-female transmission (Centers for Disease Control and Prevention, 2015h). It is at least twice as easy for a male to infect a female with any STI, including HIV, as for a female to infect a male.

As a result of school courses and media campaigns, most adolescents are aware of basic facts about HIV and AIDS. But they have limited understanding of other STIs, underestimate their own susceptibility, and are poorly informed about how to protect themselves (Kann et al., 2014). Furthermore, high school

students report engaging in oral sex much more often than intercourse, and with more partners. But few consistently use STI protection during oral sex, which is a significant mode of transmission for several STIs (Vasilenko et al., 2014). Concerted efforts are needed to educate young people about the full range of STIs and risky sexual behaviors.

## Adolescent Pregnancy and Parenthood

Cassie didn't get pregnant after having sex with Louis, but some of her classmates were less fortunate. About 625,000 U.S. teenage girls (almost 11,000 of them younger than age 15)—an estimated 13 percent of those who had sexual intercourse—became pregnant in the most recently reported year (U.S. Department of Health and Human Services, 2016a). Despite a decline of more than 50 percent since 1990, the U.S. adolescent pregnancy rate remains higher than that of most other industrialized countries (Sedgh et al., 2015).

Because about one-fourth of U.S. adolescent pregnancies end in abortion, the number of teenage births is considerably lower than it was 50 years ago (Guttmacher Institute, 2015). Still, the United States greatly exceeds most other developed nations in adolescent birth rate (see Figure 11.6). And teenage parenthood remains a problem today because contemporary adolescents rarely marry before childbirth. In 1960, only 15 percent of teenage births were to unmarried females, compared with 89 percent today (Child Trends, 2015a). Increased social acceptance of single motherhood, along with the belief of many teenage girls

that a baby might fill a void in their lives, means that very few girls give up their infants for adoption.

**Correlates and Consequences of Adolescent Parenthood.** Becoming a parent is especially challenging for adolescents, who have not yet established a clear sense of direction for their own lives. Life conditions and personal attributes jointly contribute to adolescent childbearing and also interfere with teenagers' capacity to parent effectively.

Teenage parents are far more likely to come from poverty-stricken homes than age-mates who postpone parenthood. Their backgrounds often include low parental warmth and involvement, domestic violence, child abuse and neglect, repeated parental divorce and remarriage, adult models of unmarried parenthood, and residence in neighborhoods where other adolescents also display these risks. Girls at risk for early pregnancy also do poorly in school, use drugs and alcohol, have a childhood history of aggressive and antisocial behavior, associate with deviant peers, and experience high rates of depression (Hillis et al., 2004; Luster & Haddow, 2005; Noll & Shenck, 2013). A high percentage of births are to economically disadvantaged ethnic minority teenagers. Many turn to early parenthood as a pathway to adulthood when educational and career avenues are unavailable.

The lives of expectant teenagers, already troubled in many ways, tend to worsen in several respects after the baby is born. Adolescent mothers are less likely than their peers to finish high school, get married, or secure employment. About 35 percent become pregnant again within two years; of these, about half go on to deliver a second child (Child Trends, 2015a; Ruedinger & Cox, 2012). Teenage mothers who do marry are more likely to divorce and, consequently, spend more of their child-rearing years as single parents. Because of low educational attainment, marital instability, and poverty, many teenage mothers are on welfare or work in unsatisfying, low-paid jobs.

Many adolescent fathers, too, are unemployed or work at unskilled jobs, usually earning too little to provide their children with basic necessities (Futris, Nielsen, & Olmstead, 2010). About half have been incarcerated (Elfenbein & Felice, 2003). And for both mothers and fathers, reduced educational and occupational attainment often persists well into adulthood (Taylor, 2009).

Because many pregnant teenage girls have inadequate diets, smoke, use alcohol and other drugs, and do not receive early prenatal care, their babies often experience pregnancy and birth complications—especially low birth weight (Khashan, Baker, & Kenny, 2010). And compared with adult mothers, adolescent mothers know less about child development, have unrealistically high expectations of their infants, perceive their babies as more difficult, interact less effectively with them, and more often engage in harsh or abusive parenting (Lee, 2013; Ruedinger & Cox, 2012). Their children typically score low on intelligence tests, achieve poorly in school, and engage in disruptive social behavior.

Furthermore, because adolescent parenthood is linked to a set of unfavorable family conditions and personal characteristics that negatively affect development over an extended time, it often transfers to the next generation (Meade, Kershaw, & Ickovics, 2008; Wildsmith et al., 2012). One particularly influential factor

**FIGURE 11.6** Birth rates among 15- to 19-year-olds in 15 industrialized nations. The U.S. adolescent birth rate greatly exceeds that of most other industrialized nations. (Based on Sedgh et al., 2015.)

is father absence. Consistent with findings reported earlier for sexual activity and pregnancy, far greater intergenerational continuity, especially for daughters, occurs when teenage mothers remain unmarried.

Even when children born to teenage mothers do not become early childbearers, their development is often compromised. Many drop out of school, struggle financially, and experience long-term physical and mental health difficulties. The circumstances that lead to adolescent parenthood are likely responsible for many of the negative consequences associated with it (Morinis, Carson, & Quigley, 2013; Ruedinger & Cox, 2012). Young people from severely disadvantaged backgrounds tend to experience poor social, educational, and economic outcomes; to struggle with the challenges of child rearing; and to have children with cognitive, emotional, and behavior problems, whether they give birth as teenagers or delay parenthood until their twenties.

Still, outcomes vary widely. If a teenage parent finishes high school, secures gainful employment, avoids additional births, and finds a stable partner, long-term disruptions in her own and her child's development will be less severe.

**Prevention Strategies.** Preventing teenage pregnancy means addressing the many factors underlying early sexual activity and lack of contraceptive use. Too often, sex education courses are given late (after sexual activity has begun), last only a few sessions, and are limited to a catalog of facts about anatomy and reproduction. Sex education that goes beyond this minimum does not encourage early sex, as some opponents claim (Chin et al., 2012). It does improve awareness of sexual facts—knowledge that is necessary for responsible sexual behavior.

Knowledge, however, is not enough: Sex education must also help teenagers build a bridge between what they know and what they do. Effective sex education programs include several key elements:

- They teach techniques for handling sexual situations—including refusal skills for avoiding risky sexual behaviors and communication skills for improving contraceptive use—through role-playing and other activities in which young people practice those behaviors.
- They deliver clear, accurate messages that are appropriate in view of participating adolescents' culture and sexual experiences.
- They last long enough to have an impact.
- They provide specific information about contraceptives and ready access to them.

Many studies show that sex education with these components can delay the initiation of sexual activity, increase contraceptive use, and reduce pregnancy rates (Chin et al., 2012; Kirby, 2002, 2008).

### LOOK and LISTEN

Contact a nearby public school district for information about its sex education curriculum. Considering research findings, do you think it is likely to be effective in delaying initiation of sexual activity and reducing adolescent pregnancy rates?

Proposals to increase access to contraceptives are the most controversial aspect of U.S. adolescent pregnancy prevention efforts. Many adults argue that placing birth control pills or condoms in the hands of teenagers is equivalent to approving of early sex. Yet sex education programs promoting abstinence without also advocating contraceptive use have little or no impact on delaying teenage sexual activity or preventing pregnancy (Rosenbaum, 2009; Trenholm et al., 2008). In Canada and Western Europe, where community- and school-based clinics offer adolescents contraceptives and where universal health insurance helps pay for them, teenage sexual activity is no higher than in the United States—but pregnancy, childbirth, and abortion rates are much lower (Schalet, 2007).

Efforts to prevent adolescent pregnancy and parenthood must go beyond improving sex education and access to contraception to build academic and social competence (Cornell, 2013). In a program called Teen Outreach, adolescents participated in a year-long community service class in which they spent at least 20 hours per week in volunteer work tailored to their interests, returning to school for discussions that focused on enhancing their sense of connection to the community, ability to cope with everyday challenges, social skills, and self-respect. Compared to controls in regular classes, adolescents randomly assigned to Teen Outreach displayed substantially lower end-of-year rates of pregnancy, school failure, and school suspension (Allen et al., 1997; Allen & Philliber, 2001). The program appeared most beneficial for youths at greatest risk for school failure and conduct problems, based on their history of school suspensions.

Finally, teenagers who look forward to a promising future are far less likely to engage in early and irresponsible sex. By expanding educational, vocational, and employment opportunities, society can give young people good reasons to postpone childbearing.

**Intervening with Adolescent Parents.** The most difficult and costly way to deal with adolescent parenthood is to wait until it happens. Young parents need health care, encouragement to stay in school, job training, instruction in parenting and life-management skills, and high-quality, affordable child care. Schools that provide these services reduce the incidence of low-birth-weight babies, increase educational success, and prevent additional childbearing (Cornell, 2013; Key et al., 2008).

Adolescent mothers also benefit from relationships with family members and other adults who are sensitive to their developmental needs. Those with more social support report reduced levels of depression during the year after giving birth (Brown et al., 2012). In one study, African-American teenage mothers who had a long-term “mentor” relationship—an aunt, neighbor, or teacher who provided emotional support and guidance—were far more likely than those without a mentor to stay in school and graduate (Klaw, Rhodes, & Fitzgerald, 2003). Home visiting programs are also effective. Return to page 90 in Chapter 3 to review the Nurse–Family Partnership, which helps launch teenage mothers and their babies on a favorable life course.

Programs focusing on fathers attempt to increase their financial and emotional commitment to the baby. Although half of

Early parenthood imposes lasting hardships on adolescent parents and their newborn babies. But the involvement of a caring father and a stable partnership between the parents can improve outcomes for young families.

young fathers visit their children during the first few years, contact usually diminishes over time (Ng & Kaye, 2012). As with teenage mothers, support from family members helps fathers stay involved. Mothers who receive financial and child-care assistance and emotional support from their child's father are less distressed and more likely to sustain a relationship with him (Easterbrooks et al., 2016; Gee & Rhodes, 2003). And children with lasting ties to their teenage fathers show better long-term adjustment (Martin, Brazil, & Brooks-Gunn, 2012).

## Substance Use and Abuse

At age 14, Louis waited until he was alone at home, took some cigarettes from his uncle's pack, and smoked them. At an unchaperoned party, he and Cassie drank several cans of beer and lit up marijuana joints. Louis got little physical charge out of these experiences. A good student, who was well-liked by peers and got along well with his parents, he did not need drugs as an escape valve. But he knew of other teenagers who started with alcohol and cigarettes, moved on to harder substances, and eventually were hooked.

Teenage alcohol and drug use is pervasive in industrialized nations. According to the most recent nationally representative survey of U.S. high school students, 20 percent of tenth graders have tried smoking, 47 percent drinking, and 37 percent at least one illegal drug (usually marijuana). At the end of high school, 6 percent smoke cigarettes regularly, 17 percent have engaged in heavy drinking during the past month, and 21 percent have used marijuana. About 21 percent have tried at least one highly addictive and toxic substance, such as amphetamines, cocaine, phencyclidine (PCP), Ecstasy (MDMA), inhalants, heroin, sedatives (including barbiturates), or OxyContin (a narcotic painkiller) (Johnston et al., 2015).

These figures represent a substantial decline since the mid-1990s, probably resulting from greater parent, school, and media focus on the hazards of drug taking. An exception is use of marijuana, which began to rise in the mid-2000s but has recently leveled off. Many states have passed medical use laws and a few have legalized recreational use, making it easier for young people to obtain marijuana (Johnston et al., 2015).

In part, drug taking reflects the sensation seeking of the teenage years. But adolescents also live in drug-dependent cultural contexts. They see adults relying on caffeine to stay alert, alcohol and cigarettes to cope with daily hassles, and other remedies to relieve stress, depression, and physical discomfort. They also encounter high rates of cigarette, alcohol, and drug use in TV programs, movies, and advertisements (Strasburger, 2012). And compared to a decade or two ago, today doctors more often prescribe—and parents frequently seek—medication to treat children's problems (Olfman & Robbins, 2012). In adolescence, these young people may readily “self-medicate” when stressed.

Most teenagers who try alcohol, tobacco, or marijuana are not headed for a life of addiction. These *occasional experimenters* are usually psychologically healthy, sociable, curious young people. Nevertheless, adolescent experimentation with any drug should not be taken lightly. Because most drugs impair perception and thought processes, a single heavy dose can lead to permanent injury or death. And a worrisome minority of teenagers move from substance *use* to *abuse*—taking drugs regularly, requiring increasing amounts to achieve the same effect, moving on to harder substances, and using enough to interfere with their ability to meet daily responsibilities.

## Correlates and Consequences of Adolescent Substance Abuse.

Unlike experimenters, drug abusers are seriously troubled young people. Their impulsive, disruptive, hostile style is often evident in early childhood, and they are inclined to express their unhappiness through antisocial acts. Compared with other young people, their drug taking starts earlier and may have genetic roots (Patrick & Schulenberg, 2014). In a longitudinal study of ethnically diverse early adolescents, a large imbalance between the brain's cognitive-control network and its emotional/social network—indicated by weak executive function against elevated sensation seeking of this period—predicted a rapid rise in alcohol, tobacco, and marijuana use by midadolescence (see Figure 11.7) (Khurana et al., 2015). These teenagers, at high risk of becoming abusers, contrasted sharply with minimal experimenters and nonusers, who displayed similar sensation seeking but much stronger cognitive control.

But environmental factors also contribute. These include low SES, family mental health problems, parental and older sibling drug abuse, lack of parental warmth and involvement, physical and sexual abuse, and poor school performance. Especially among teenagers with family difficulties, encouragement from friends who use and provide drugs increases substance abuse (Ohannessian & Hesselbrock, 2008; Patrick & Schulenberg, 2014).

Introducing drugs while the adolescent brain is still a work-in-progress can have profound, lasting consequences, impairing

**FIGURE 11.7 Weak cognitive control predicts a rapid rise in drug use from early to middle adolescence.** When several hundred ethnically diverse adolescents were followed from early to middle adolescence, a large imbalance between the brain’s cognitive-control network and emotional/social network (weak executive function against high sensation seeking) predicted a dramatic rise in drug taking, signifying high risk for abuse. Elevated sensation seeking against strong cognitive control predicted minimal use or nonuse over time (Based on Khurana et al., 2015.)

neurons and their connective networks. At the same time, teenagers who use substances to deal with daily stresses fail to learn responsible decision-making skills and alternative coping techniques. They show serious adjustment problems, including chronic anxiety, depression, and antisocial behavior, that are both cause and consequence of heavy drug taking (Kassel et al., 2005; Luciana et al., 2013). And they often enter into marriage, child-bearing, and the work world prematurely and fail at these challenges—painful outcomes that further promote addictive behavior.

**Prevention and Treatment.** School and community programs that reduce drug experimentation typically combine several components:

- They promote effective parenting, including monitoring of teenagers’ activities.
- They teach skills for resisting peer pressure.
- They reduce the social acceptability of drug taking by emphasizing health and safety risks (Stephens et al., 2009).

One intervention, the Strong African American Families (SAAF) program, teaches parents to monitor their adolescents’ behavior, communicate and enforce clear expectations, and use cooperative problem solving to resolve disputes. Evaluations revealed that SAAF reduced substance use among African-American youths, and it was most effective for adolescents with the DRD4 7-repeat or the short 5-HTTLPR gene (see pages 194 and 201 in Chapter 6), which placed them at risk for self-regulation difficulties (Brody et al., 2009, 2014). Does this remind you of evidence discussed in previous chapters indicating that good parenting can protect the development of genetically vulnerable children?

STRONG AFRICAN-AMERICAN FAMILIES PROGRAM (SAAF), CENTER FOR FAMILY RESEARCH, THE UNIVERSITY OF GEORGIA

The Strong African American Families (SAAF) program strengthens parent–adolescent relationships through discussions like this one, which pave the way toward more effective parenting, including communicating and enforcing clear expectations and resolving disputes through cooperative problem solving.

Programs that teach at-risk teenagers effective strategies for handling life stressors and that build competence through community service reduce alcohol and drug use, just as they reduce teenage pregnancy. Providing appealing substitute activities is also helpful. Physical activity works especially well as a substitute for cigarette smoking. In a program aimed at helping teenagers stop smoking, participants were most likely to cut back or quit when the intervention also helped them exercise more (Horn et al., 2013).

When an adolescent becomes a drug abuser, family and individual therapy are generally needed to treat maladaptive parent–child relationships, impulsivity, low self-esteem, anxiety, and depression. Academic and vocational training to improve life success also helps. But even comprehensive programs have alarmingly high relapse rates—from 35 to 85 percent (Brown & Ramo, 2005; Sussman, Skara, & Ames, 2008).

Adolescents who are motivated at the start of treatment have better outcomes (Joe et al., 2014). One recommendation is to initiate treatment gradually, through support-group sessions that focus on reducing drug taking. Modest improvements may boost the young person’s sense of self-efficacy for behavior change and, as a result, increase motivation to make longer-lasting changes through intensive treatment.

## Ask yourself

**CONNECT** What adverse personal attributes and life conditions do teenagers who engage in early and frequent sexual activity have in common with those who abuse drugs?

**APPLY** After 17-year-old Veronica gave birth to Ben, her parents told her they didn’t have room for the baby. Veronica dropped out of school and moved in with her boyfriend, who soon left. Why are Veronica and Ben likely to experience long-term hardships?

**REFLECT** Describe your experiences with peer pressure to experiment with alcohol and drugs. What factors influenced your response?

## COGNITIVE DEVELOPMENT

One mid-December evening, a knock at the front door announced the arrival of Franca and Antonio's oldest son, Jules, home for vacation after the fall semester of his sophomore year at college. The family gathered around the kitchen table. "How did it all go, Jules?" asked Antonio as he served slices of apple pie.

"Well, physics and philosophy were awesome," Jules responded with enthusiasm. "The last few weeks, our physics prof introduced us to Einstein's theory of relativity. Boggles my mind, it's so incredibly counterintuitive."

"Counter-what?" asked 11-year-old Sabrina.

"Counterintuitive. Unlike what you'd normally expect," explained Jules. "Imagine you're on a train, going unbelievably fast, like 160,000 miles a second. The faster you go, approaching the speed of light, the slower time passes and the denser and heavier things get relative to on the ground. The theory revolutionized the way we think about time, space, matter—the entire universe."

Sabrina wrinkled her forehead, baffled by Jules's otherworldly reasoning. "Time slows down when I'm bored, like right now, not on a train when I'm going somewhere exciting. No speeding train ever made me heavier, but this apple pie will if I eat any more of it," Sabrina announced, leaving the table.

Sixteen-year-old Louis reacted differently. "Totally cool, Jules. So what'd you do in philosophy?"

"It was a course in philosophy of technology. We studied the ethics of futuristic methods in human reproduction. For example, we argued the pros and cons of a world in which all embryos develop in artificial wombs."

"What do you mean?" asked Louis. "You order your kid at the lab?"

"That's right. I wrote my term paper on it. I had to evaluate it in terms of principles of justice and freedom. I can see some advantages but also lots of dangers. . . ."

As this conversation illustrates, adolescence brings with it vastly expanded powers of reasoning. At age 11, Sabrina finds it difficult to move beyond her firsthand experiences to a world of possibilities. During the coming years, her thinking will acquire the complex qualities that characterize the cognition of her older brothers. Jules and Louis consider multiple variables simultaneously and think about situations that are not easily detected in the real world or that do not exist at all. As a result, they can grasp advanced scientific and mathematical principles and grapple with social and political issues. Compared with school-age children's thinking, adolescent thought is more enlightened, imaginative, and rational.

Systematic research on adolescent cognitive development began with testing of Piaget's ideas (Keating, 2012; Kuhn, 2009). Information-processing research has greatly enhanced our understanding.

## Piaget's Theory: The Formal Operational Stage

**11.12** What are the major characteristics of formal operational thought?

**11.13** Discuss follow-up research on formal operational thought and its implications for the accuracy of Piaget's formal operational stage.

According to Piaget, around age 11 young people enter the **formal operational stage**, in which they develop the capacity for abstract, systematic, scientific thinking. Whereas concrete operational children can "operate on reality," formal operational adolescents can "operate on operations." They no longer require concrete things or events as objects of thought. Instead, they can come up with new, more general logical rules through internal reflection (Inhelder & Piaget, 1955/1958). Let's look at two major features of the formal operational stage.

### Hypothetico-Deductive Reasoning

Piaget believed that at adolescence, young people first become capable of **hypothetico-deductive reasoning**. When faced with a problem, they start with a *hypothesis*, or prediction about variables that might affect an outcome, from which they *deduce* logical, testable inferences. Then they systematically isolate and combine variables to see which of these inferences are confirmed in the real world. Notice how this form of problem solving begins with possibility and proceeds to reality. In contrast, concrete operational children start with reality—with the most obvious predictions about a situation. If these are not confirmed, they usually cannot think of alternatives and fail to solve the problem.

Adolescents' performance on Piaget's famous *pendulum problem* illustrates this approach. Suppose we present several school-age children and adolescents with strings of different lengths, objects of different weights to attach to the strings, and a bar from which to hang the strings (see Figure 11.8). Then we ask each of them to figure out what influences the speed with which a pendulum swings through its arc.

Formal operational adolescents hypothesize that four variables might be influential: (1) the length of the string, (2) the weight of the object hung on it, (3) how high the object is raised before it is released, and (4) how forcefully the object is pushed. By varying one factor at a time while holding the other three constant, they test each variable separately and, if necessary, also in combination. Eventually they discover that only string length makes a difference.

In contrast, concrete operational children cannot separate the effects of each variable. They may test for the effect of string length without holding weight constant—comparing, for example, a short, light pendulum with a long, heavy one. Also, they typically fail to notice variables that are not immediately suggested by the concrete materials of the task—for example, how high the object is raised or how forcefully it is released.

**FIGURE 11.8** Piaget’s pendulum problem. Adolescents who engage in hypothetico-deductive reasoning think of variables that might possibly affect the speed with which a pendulum swings through its arc. Then they isolate and test each variable, as well as testing the variables in combination. Eventually they deduce that the weight of the object, the height from which it is released, and how forcefully it is pushed have no effect on the speed with which the pendulum swings through its arc. Only string length makes a difference.

## Propositional Thought

A second important characteristic of Piaget’s formal operational stage is **propositional thought**—adolescents’ ability to evaluate the logic of propositions (verbal statements) without referring to real-world circumstances. In contrast, children can evaluate the logic of statements only by considering them against concrete evidence in the real world.

In a study of propositional reasoning, a researcher showed children and adolescents a pile of poker chips and asked whether statements about the chips were true, false, or uncertain (Osherson & Markman, 1975). In one condition, the researcher hid a chip in her hand and presented the following propositions:

“Either the chip in my hand is green or it is not green.”

“The chip in my hand is green *and* it is not green.”

In another condition, the experimenter made the same statements while holding either a red or a green chip in full view.

School-age children focused on the concrete properties of the poker chips. When the chip was hidden, they replied that they were uncertain about both statements. When it was visible, they judged both statements to be true if the chip was green and false if it was red. In contrast, most adolescents analyzed the logic of the statements. They understood that the “either-or” statement is always true and the “and” statement is always false, regardless of the chip’s color.

Although Piaget did not view language as playing a central role in children’s cognitive development (see Chapter 7), he acknowledged its importance in adolescence. Formal operations require language-based and other symbolic systems that do not stand for real things, such as those in higher mathematics. Secondary school students use such systems in algebra and geometry. Formal operational thought also involves verbal reasoning about abstract concepts. Jules was thinking in this way when he pondered relationships among time, space, and matter in physics and wondered about justice and freedom in philosophy.

## Follow-Up Research on Formal Operational Thought

Research on formal operational thought poses questions similar to those we discussed with respect to Piaget’s earlier stages: Does formal operational thinking appear earlier than Piaget expected? Do all individuals reach formal operations during their teenage years?

### Are Children Capable of Hypothetico-Deductive and Propositional Thinking?

School-age children show the glimmerings of hypothetico-deductive reasoning, although they are less competent at it than adolescents. In simplified situations involving no more than two possible causal variables, 6-year-olds understand that hypotheses must be confirmed by appropriate evidence (Ruffman et al., 1993). But without direct instruction, school-age children cannot sort out evidence that bears on three or more variables at once (Lorch et al., 2010; Matlen & Klahr, 2013). And as we will see when we take up information-processing research, children have difficulty explaining why a pattern of observations supports a hypothesis, even when they recognize the connection between the two.

With respect to propositional thought, when a simple set of premises defies real-world knowledge (“All cats bark. Rex is a cat. Does Rex bark?”) but is presented with the support of props in make-believe play, 4- to 6-year-olds can reason logically. To justify their answer, they are likely to say, “We can pretend cats bark!” (Dias & Harris, 1988, 1990). But in an entirely verbal mode, children have great difficulty reasoning from premises that contradict reality or their own beliefs.

Consider this set of statements: “If dogs are bigger than elephants and elephants are bigger than mice, then dogs are bigger than mice.” Children younger than 10 judge this reasoning to be false because some of the relations specified do not occur in real life (Moshman & Franks, 1986; Pillow, 2002). They automatically think of well-learned knowledge (“Elephants are larger than dogs”) that casts doubt on the truthfulness of the premises. Children find it more difficult than adolescents to inhibit activation of such knowledge (Klaczynski, Schuneman, & Daniel, 2004; Simoneau & Markovits, 2003). Partly for this reason, they fail to grasp the *logical necessity* of propositional reasoning—that the accuracy of conclusions drawn from premises rests on the rules of logic, not on real-world confirmation.

© LAURA DWIGHT PHOTOGRAPHY

Adolescents gradually improve in propositional thought. As these students discuss problems in a social studies class, they show that they can analyze the logic of propositions, independent of their content.

As with hypothetico-deductive reasoning, in early adolescence, young people become better at analyzing the *logic* of propositions, regardless of their *content*. And they handle problems requiring increasingly complex mental operations. In justifying their reasoning, they more often explain the logical rules on which it is based (Müller, Overton, & Reese, 2001; Venet & Markovits, 2001). But these capacities do not appear suddenly at puberty. Rather, gains are gradual from childhood on—findings that call into question the emergence of a new stage of cognitive development at adolescence (Kuhn, 2009; Moshman, 2005).

**Do All Individuals Reach the Formal Operational Stage?** Try giving one or two of the formal operational tasks just described to your friends. How well do they do? Even well-educated adults often have difficulty (Kuhn, 2009; Markovits & Vachon, 1990).

Why are so many adults not fully formal operational? One reason is that people are most likely to think abstractly and systematically on tasks in which they have had extensive guidance and practice in using such reasoning (Kuhn, 2013). This conclusion is supported by evidence that taking college courses leads to improvements in formal reasoning related to course content. Math and science prompt gains in propositional thought, social science in methodological and statistical reasoning (Lehman & Nisbett, 1990). Like concrete reasoning in children, formal operations do not emerge in all contexts at once but are specific to situation and task (Keating, 2004, 2012).

Individuals in tribal and village societies rarely do well on tasks typically used to assess formal operational reasoning (Cole, 1990). Piaget acknowledged that without the opportunity to solve hypothetical problems, people in some societies might not display formal operations. Still, researchers ask, Does formal operational thought largely result from children's and adolescents' independent efforts to make sense of their world, as Piaget claimed? Or is it a culturally transmitted way of thinking that is specific to literate societies and taught in school?

In an Israeli study of seventh to ninth graders, after controlling for participants' age, researchers found that years of schooling fully accounted for early adolescent gains in propositional thought (Artman, Cahan, & Avni-Babad, 2006). School tasks, the investigators speculated, provide crucial experiences in setting aside the “if ... then” logic of everyday conversations that is often used to convey intentions, promises, and threats (“If you don't do your chores, then you won't get your allowance”) but that conflicts with the logic of academic reasoning. In school, then, adolescents encounter rich opportunities to realize their neurological potential to think more effectively.

## An Information-Processing View of Adolescent Cognitive Development

**11.14** How do information-processing researchers account for cognitive changes in adolescence?

Information-processing theorists refer to a variety of specific mechanisms, including components of executive function, as underlying cognitive gains in adolescence. As noted in previous chapters, each mechanism promotes advances in others (Keating, 2012; Kuhn, 2009, 2013; Kuhn & Franklin, 2006). Now let's draw them together:

- *Working memory* increases, enabling more information to be held in mind at once and combined into increasingly complex, efficient representations, “opening possibilities for growth” in the capacities listed below and also improving as a result of gains in those capacities (Demetriou et al., 2002, p. 97).
- *Inhibition*—both of irrelevant stimuli and of well-learned responses in situations where they are inappropriate—improves, supporting gains in attention and reasoning.
- *Attention* becomes more *selective* (focused on relevant information) and *flexible*—better-adapted to the changing demands of tasks.
- *Planning* on complex tasks with multiple steps improves, becoming better-organized and efficient.
- *Strategies* become more effective, enhancing storage, representation, and retrieval of information.
- *Knowledge* increases, easing strategy use.
- *Metacognition* (awareness of thought) expands, leading to new insights into effective strategies for acquiring information and solving problems.
- *Cognitive self-regulation* improves, yielding better moment-by-moment monitoring, evaluation, and redirection of thinking.

As we look at influential findings from an information-processing perspective, we will see some of these changes in action. And we will discover that researchers regard one of them—*metacognition*—as central to adolescent cognitive development.

## Scientific Reasoning: Coordinating Theory with Evidence

During a free moment in physical education class, Sabrina wondered why more of her tennis serves and returns passed the net and dropped in her opponent's court when she used a particular brand of balls. "Is it something about their color or size?" she asked herself. "Hmm ... or maybe it's their surface texture—that might affect their bounce."

The heart of scientific reasoning is coordinating theories with evidence. Researchers have conducted extensive research into the development of scientific reasoning, using problems that, like Piaget's tasks, involve several variables that, alone or in combination, might affect an outcome (Lehrer & Schauble, 2015). How does evaluation of theories in light of evidence change with age?

In one series of studies, third, sixth, and ninth graders and adults were first presented with evidence—sometimes consistent and sometimes conflicting with theories—and then questioned about the accuracy of each theory (Kuhn, 2002). For example, participants were given a problem much like Sabrina's: to theorize about which of several features of sports balls—size (large or small), color (light or dark), texture (rough or smooth), or presence or absence of ridges on the surface—influences the quality of a player's serve. Next, they were told about the theory of Mr. (or Ms.) S, who believes the ball's size is important, and the theory of Mr. (or Ms.) C, who thinks color matters. Finally, the interviewer presented evidence by placing balls with certain characteristics in two baskets, labeled "good serve" and "bad serve" (see Figure 11.9).

The youngest participants often discounted obviously causal variables, ignored evidence conflicting with their own initial judgment, and distorted evidence in ways consistent with their preferred theory. These findings, and others like them, suggest that on complex, multivariable tasks, children—instead of viewing evidence as separate from and bearing on a theory—often blend the two into a single representation of "the way things are." Children are especially likely to overlook evidence that does not match their prior beliefs when a causal variable is implausible (like color affecting the performance of a sports ball) and when task demands (number of variables to be evaluated) are high (Yang & Tsai, 2010). The ability to distinguish theory from evidence and use logical rules to examine their relationship improves steadily from childhood into adolescence, continuing into adulthood (Kuhn & Dean, 2004; Zimmerman & Croker, 2013).

## How Scientific Reasoning Develops

What factors support skill at coordinating theory with evidence? Greater working-memory capacity, permitting a theory and the effects of several variables to be compared at once, is vital. Adolescents also benefit from exposure to increasingly complex problems and to instruction that highlights critical features of scientific reasoning—for example, why a scientist's expectations in a particular situation are inconsistent with everyday beliefs and experiences (Chinn & Malhotra, 2002). This explains why scientific reasoning is strongly influenced by years of schooling, whether individuals grapple with traditional scientific tasks (like

**FIGURE 11.9** Which features of these sports balls—size, color, surface texture, or presence or absence of ridges—influence the quality of a player's serve? This set of evidence suggests that color might be important, since light-colored balls are largely in the good-serve basket and dark-colored balls in the bad-serve basket. But the same is true for texture! The good-serve basket has mostly smooth balls; the bad-serve basket, rough balls. Since all light-colored balls are smooth and all dark-colored balls are rough, we cannot tell whether color or texture makes a difference. But we can conclude that size and presence or absence of ridges are not important, since these features are equally represented in the good-serve and bad-serve baskets. (Adapted from Kuhn, Amsel, & O'Loughlin, 1988.)

the sports-ball problem) or engage in informal reasoning—for example, justifying a theory about what causes children to fail in school (Amsel & Brock, 1996).

Sophisticated *metacognitive understanding* is vital for scientific reasoning (Kuhn, 2011, 2013). When adolescents regularly pit theory against evidence over many weeks, they experiment with various strategies, reflect on and revise them, and become aware of the nature of logic. Then they apply their appreciation of logic to an increasingly wide variety of situations. The ability to think about theories, deliberately isolate and control variables, and inhibit an initial choice long enough to actively seek disconfirming evidence and weigh alternative possibilities is rarely present before adolescence (Kuhn, 2000; Kuhn et al., 2008; Moshman, 1998).

Though far more competent than children, adolescents and adults vary widely in scientific reasoning skills (Kuhn, 2011). Many continue to show a self-serving bias, applying logic more effectively to ideas they doubt than to ideas they favor. Reasoning scientifically requires the metacognitive capacity to evaluate one's objectivity—to be fair-minded rather than self-serving (Moshman, 2011). As we will see in Chapter 12, this flexible, open-minded approach is not just a cognitive attainment but a personality trait—one that assists teenagers greatly in forming an identity and developing morally.

Adolescents develop scientific reasoning skills in a similar step-by-step fashion on different types of tasks. In a series of

studies, 10- to 20-year-olds were given sets of problems graded in difficulty. One set contained causal-experimental tasks like the sports-ball problem in Figure 11.9, another contained quantitative-relational tasks like the pendulum problem in Figure 11.8, and still another consisted of propositional tasks like the poker chip problem on page 389 (Demetriou et al., 1993, 1996, 2002). In each type of task, adolescents mastered component skills in sequential order by expanding their metacognitive awareness. For example, on causal-experimental tasks, they first became aware of the many variables that—separately and in combination—could influence an outcome. This enabled them to formulate and test hypotheses. Over time, adolescents combined separate skills into a smoothly functioning system, constructing a general model that they could apply to many instances of a given type of problem.

### LOOK and LISTEN

Describe one or more memorable experiences from your high school classes that helped you advance in scientific reasoning—pit theory against evidence and become receptive to disconfirming evidence, even for theories you favored.

Piaget underscored the role of metacognition in formal operational thought when he spoke of “operating on operations” (see page 388). But information-processing findings confirm that scientific reasoning does not result from an abrupt, stagewise change. Instead, it develops gradually out of many specific experiences that require children and adolescents to match theories against evidence and reflect on and evaluate their thinking.

## Consequences of Adolescent Cognitive Changes

**11.15** Describe typical reactions of adolescents that result from their advancing cognition.

The development of increasingly complex, effective thinking leads to dramatic revisions in the way adolescents see themselves, others, and the world in general. But just as adolescents are occasionally awkward in using their transformed bodies, so they initially falter in their abstract thinking. Teenagers’ self-concern, idealism, criticism, and faulty decision making, though perplexing to adults, are usually beneficial in the long run. Applying What We Know on the following page suggests ways to handle the everyday consequences of teenagers’ newfound cognitive capacities.

### Self-Consciousness and Self-Focusing

Adolescents’ ability to reflect on their own thoughts, combined with physical and psychological changes, leads them to think more about themselves. Piaget believed that a new form of egocentrism arises, in which adolescents again have difficulty distinguishing their own and others’ perspectives (Inhelder & Piaget,

1955/1958). Piaget’s followers suggest that two distorted images of the relation between self and other appear.

The first is called the **imaginary audience**, adolescents’ belief that they are the focus of everyone else’s attention and concern (Elkind & Bowen, 1979). As a result, they become extremely self-conscious. The imaginary audience helps explain why adolescents spend long hours inspecting every detail of their appearance and why they are so sensitive to public criticism. To teenagers, who believe that everyone is monitoring their performance, a critical remark from a parent or teacher can be mortifying.

A second cognitive distortion is the **personal fable**. Certain that others are observing and thinking about them, teenagers develop an inflated opinion of their own importance—a feeling that they are special and unique. Many adolescents view themselves as reaching great heights of omnipotence and also sinking to unusual depths of despair—experiences that others cannot possibly understand (Elkind, 1994). One teenager wrote in her diary, “My parents’ lives are so ordinary, so stuck in a rut. Mine will be different. I’ll realize my hopes and ambitions.” Another, upset when a boyfriend failed to return her affections, rebuffed her mother’s comforting words: “Mom, you don’t know what it’s like to be in love!”

Although imaginary-audience and personal-fable ideation is common in adolescence, these distorted visions of the self do not result from egocentrism, as Piaget suggested. Rather, they are partly an outgrowth of advances in perspective taking, which cause young teenagers to be more concerned with what others think (Vartanian & Powlishta, 1996). Recall, also, that changes in the brain’s emotional/social network spark increased sensitivity to social feedback.

In fact, certain aspects of the imaginary audience may serve positive, protective functions. When asked why they worry about the views of others, adolescents responded that others’ evaluations have important *real* consequences—for self-esteem, peer

© DOCCO DALFIANO/ROBERT HARDING

This teenager appears self-confident and delighted that all eyes are on him. When the personal fable engenders a view of oneself as highly capable and influential, it may help young people cope with the challenges of adolescence.

## Applying what we Know

### Handling Consequences of Teenagers' New Cognitive Capacities

THOUGHT EXPRESSED AS ...	SUGGESTION
Sensitivity to public criticism	Avoid finding fault with the adolescent in front of others. If the matter is important, wait until you can speak to the teenager alone.
